Identification of the origin of AIDS followed closely behind the clinical description of this complex immunodeficiency. In 1983, investigators worldwide identified a viral cause for AIDS and described human lymphotropic virus III, lymphadenopathy-associated virus, and a virus associated with persistent generalized lymphadenopathy.[58,93] These viruses subsequently were identified as similar and now are called HIV-1, or simply HIV (Fig. 191B-1).[66] Two species of HIV are recognized: HIV-1 and HIV-2. HIV-1 has been the more prevalent pathogenic species and, especially in the United States, almost uniformly has been associated with reported AIDS cases. Viral divergence is not uncommon, and HIV-1 can be divided into three groups: M, major; O, outliers; and N, non-M/non-O; the M group represents the major group with subtypes (clades) showing significant symmetry.[116] The major subtypes have been identified, and data from the WHO HIV Vaccine Initiative identified clade C in 50 percent of global infections in 2004.[116] Clade B is identified most frequently in industrialized countries, including the United States. In 2004, recombinant subtypes were responsible for 18 percent of worldwide infections; continued collection of such data will be important in the successful development of a vaccine that can be applied universally to stem transmission of HIV. A detailed description of these RNA viruses, their method of viral introduction into the affected host, and their impact on critical immune components is provided in Chapter 191A.

PATHOGENESIS

The Developing Immune System

In perinatally infected infants, the disruption that HIV creates in the fetal/neonatal immune system is envisioned best by considering the intricate normal differentiation pathways of the bone marrow stem cell.[269] T- and B-lymphocyte differentiation pathways are presented in Figure 191B-2 to illustrate points where genetic defects can occur and then cause congenital immunodeficiency. In many regards, the immunodeficiency of neonatal HIV infection parallels that of genetically inherited immune disorders.

HIV affects almost all immune cell types and alters their ability to produce important chemokines and interleukins that are integral to immunologic homeostasis. Independent of cell damage, host response also can vary according to individual genetic HLA representation and predict either probability of infection occurring after exposure or progression of disease.[80] $CD4^+$ cells bear a receptor (the $CD4^+$ molecule itself) for the gp120 component of the HIV virion coat, and through this mechanism viral entry into the host cell is allowed. This entry does not occur in isolation, and host expression of a

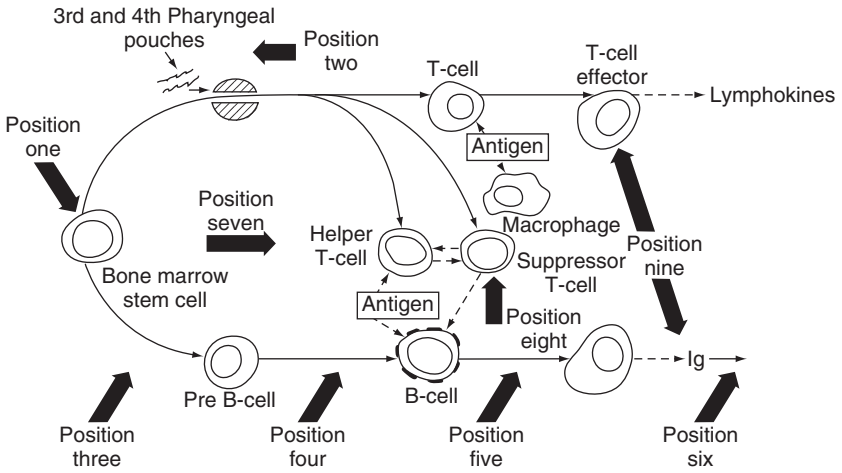

FIGURE 191B-2 ■ Model of the events of cellular maturation, cellular interaction, and cellular biosynthesis required for a normal immune response. The *arrows* indicate presumed defects in various immunodeficiency states. *Position 1,* Failure of B- and T-cell development (e.g., severe combined immunodeficiency disease). *Position 2,* Failure of development of the thymus (e.g., DiGeorge syndrome). *Position 3,* Failure of maturation of stem cells into pre-B cells (e.g., thymoma, hypogammaglobulinemia). *Position 4,* Failure of maturation of pre-B cells into B cells (e.g., X-linked hypogammaglobulinemia). *Position 5,* Failure of maturation of B cells into plasma cells (e.g., common variable hypogammaglobulinemia). *Position 6,* Hypercatabolism of immunoglobulin (e.g., myotonic dystrophy). *Position 7,* Reduced helper T cells (e.g., subset of common variable hypogammaglobulinemia). *Position 8,* Increase in suppressor T-cell activity (e.g., subset of common variable hypogammaglobulinemia). *Position 9,* Excessive loss of immunoglobulins and lymphocytes (e.g., intestinal lymphangiectasia). (From Waldmann TA. Immunodeficiency diseases: primary and acquired. In: Samter M, Talmage DW, Frank MM, et al., editors. *Immunological diseases.* 4th ed. Boston: Little, Brown; 1988, p. 411-65.)

chemokine receptor (CXCR4 for T-lymphotropic HIV strains; CCR5 for monocyte tropic HIV strains) interacts in promoting viral particle binding to the host cell membrane and release of viral particles into the cytoplasm.[55] Data suggest that heterozygous allele expression of these coreceptors may affect expression and progression of HIV disease. Density expression of CCR5 molecules in infants has been correlated with progression of disease even in the presence of antiretroviral therapy and with the slope of $CD4^+$ cell decline from birth.[49]

Once infected, the infant with perinatal transmission exhibits a quick rise in detectable HIV viral load that can exceed 750,000 copies/mL in the first weeks or months of life and persists unchecked without institution of antiviral therapy through the first years of life.[3] This persistent and lengthy viremia in early perinatal HIV infection differs from acute HIV-1 infection in adults, in which viremia initially may be equally elevated but abates with host immunologic response (albeit without complete elimination) over the course of a shorter time frame (weeks to months). These distinctions in host response reflect the more ineffective infant immunologic host response to HIV infection. Proposed mechanisms of immune dysfunction associated with continued viremia in infants include thymic damage with thymocyte depletion, disruption of thymic architecture, early $CD4^+$ cell depletion that affects $CD8^+$ cell response to HIV antigens, early lymphocyte activation as measured by $CD8^+DR^+CD38^+$ T cells that impede effective host T-cell response, and genetic predisposition to allow enhanced HIV entry into host cells.[226,280] Most clinicians opt for early treatment of HIV-infected infants younger than 1 year of age, independent of the clinical or immunologic ($CD4^+$ cell count) presentation. Studies have documented that early therapy slows immune system destruction and preserves immune function, preventing clinical disease progression.[53]

Immune Dysfunction

Abnormalities in adult HIV infection include leukopenia, lymphopenia, and decreased $CD4^+$ helper-inducer cells with an expanded $CD8^+$ cell population, which results in an inverted CD4/CD8 ratio, typically less than 1.0. Early in the course of infection, T-lymphocyte function has been noted to be diminished (<50%), with decreased in vitro responses to soluble antigens preceding $CD4^+$ cell depletion. Although in vitro responses to plant lectins, such as phytohemagglutinin, concanavalin A, and pokeweed, appear to be normal early in the course of HIV infection, these responses begin to decrease with clinical decline; characteristically, mitogen responses to pokeweed disappear first. Anergy is not unusual to commonly tested antigens (tetanus, *Candida*). Levels of proinflammatory cytokines (interleukin [IL]-1, IL-6, IL-8) increase whereas levels of T-helper type 1 (Th1) cytokines (IL-2, tumor necrosis factor-α, interferon-γ, IL-12) decrease. Proinflammatory cytokines appear to induce viral replication by activating the host cell.[59] In addition, HIV-infected $CD4^+$ cells release soluble IL-2 receptors. These elevated serum IL-2 receptor levels produce a blockade of cell-bound IL-2 receptors by competition for IL-2. $CD8^+$ cell response to HIV-specific antigens is impaired.[197] Children with HIV infection seldom are lymphopenic in terms of values observed in adults. If lymphopenia is observed in children with HIV infection, it usually is seen in older children or in children who have progressed to end-stage HIV disease. In fact, $CD4^+$ cell counts in HIV-infected children commonly exceed 400 cells/mm^3. Moreover, Denny and associates[68] showed that in infants

aged 12 to 24 months, a $CD4^+$ cell value of less than 1000 cells/mm^3 is significant for selective HIV-related $CD4^+$ depletion. In infants younger than 12 months, a value of less than 1500 cells/mm^3 similarly applies. Lymphoproliferative responses to recall antigens have been documented as relatively normal findings early in the course of infection; decline is correlated with the onset of clinical symptoms. As described earlier in discussions of pathogenesis, HIV-1-specific $CD8^+$ cytotoxic-suppressor cell function has been documented as being ineffective in infants with primary infection (early perinatal infection).

After administration of HAART, T-cell function against specific HIV antigens continues to be imperfect. Despite lowering of viral load, $CD4^+$ cell depletion may not be completely restored for many weeks. Differential restoration of subpopulations of $CD4^+$ cells (effector memory cells more commonly encountered than naïve cells) may occur. In 643 children with significant $CD4^+$ depletion ($CD4^+$ cells <250 cells/mm^3) and viremia, HAART resulted in a median rise of $CD4^+$ cell count of 100 cells/mm^3 over the course of 2 years, but anergy was reported in 80 percent, lack of proliferative response to the specific antigen of tetanus in 73 percent, and impaired serologic response to hepatitis A virus vaccination in 54 percent.[153] Hence, despite administration of antiretroviral therapy, T-cell immune restoration may not be complete in all affected children.

B-cell dysfunction is identified similarly in HIV-infected adults and children and manifests as hypergammaglobulinemia. HIV-infected adults also demonstrate circulating immune complexes and production of autoantibodies secondary to polyclonal activation of B cells by HIV itself or concomitant viral infection with cytomegalovirus (CMV) or Epstein-Barr virus (EBV).[150] In particular, immunoglobulin G (IgG) levels may rise to 2 to 3 standard deviations above the mean of normal values, and serum IgA, IgM, and IgE levels may be elevated as well. This extreme hypergammaglobulinemia in children may be caused by polyclonal stimulation of B cells by HIV or coinfection with CMV or EBV, or it may be caused by the absence of normal $CD4^+$ immunoregulatory cells. Specific antibody functions measured as childhood vaccine responses often are abnormal and are not always completely restored in the most severely immunocompromised individuals after administration of HAART therapy.[153]

Other host defense cells affected by HIV infection include natural killer (NK) cells. In adults with chronic HIV infection, reported NK cell abnormalities include differential representation of certain NK cell subpopulations, downregulation of NK ligand expression that affects cytotoxicity of HIV-infected cells, and NK cell/dendritic cell (DC) interactions. Human DCs contain two subsets: myeloid and plasmacytoid DCs. Both subsets have additional roles in HIV infection that lead to viral elimination or control.[6] Activated myeloid DCs produce cytokines such as IL-12, IL-15, and IL-18. IL-12 is critical for myeloid DCs to induce Th1 cell responses, which subsequently promote potent cytotoxic T-lymphocyte responses that are necessary for clearing virus-infected cells.[151] Plasmacytoid DCs produce more type I interferons (IFNs) in response to HIV than any other cell in the body and stimulate myeloid DCs in a bystander fashion as well as directly activating NK cells.[218] The implications of these events underlie the need to develop vaccine strategies that enhance the ability of DCs to prime potent T-cell responses that can subvert the potential inhibitory effects of HIV on the immune system. Monocytes and macrophages play important roles in the pathogenesis of HIV infection by serving as reservoirs of HIV. Defective chemotaxis and bacterial killing have been observed in HIV-infected monocytes and macrophages, as has defective induction of IL-1, which possibly accounts for the decreased IL-2 response in $CD4^+$ cells.[279] The immune system also seems to contribute directly to HIV-induced encephalopathy (Fig. 191B-3).[26,118] HIV-induced encephalopathy is particularly devastating in young infants, who fail to reach early motor milestones or, worse, regress from acquired early development. The incomplete state of myelination of central nervous system (CNS) tissue may account for susceptibility to the

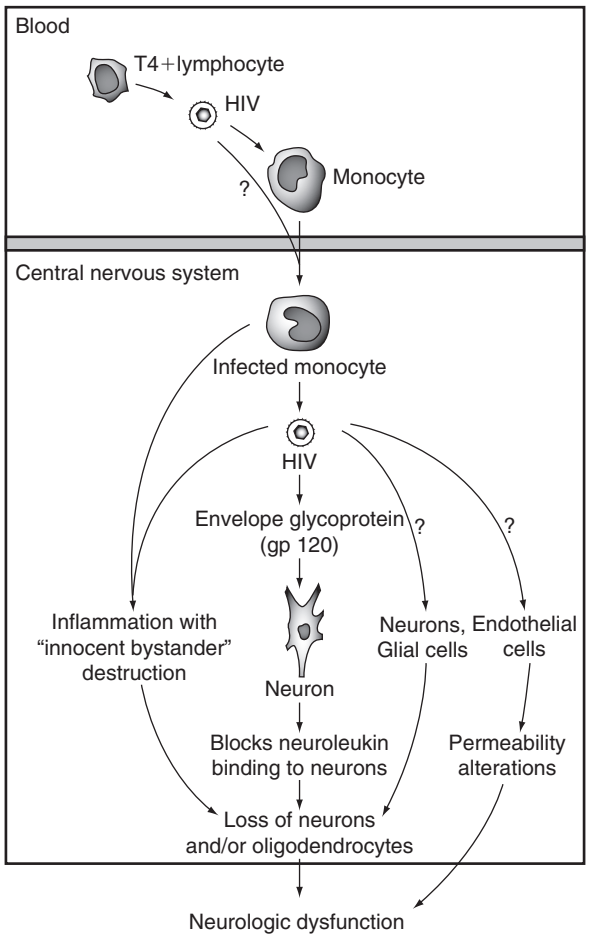

FIGURE 191B-3 ■ Role of the immune system in pediatric human immunodeficiency virus (HIV)–induced encephalopathy. HIV-infected $CD4^+$ lymphocytes and macrophages enter the central nervous system. HIV may escape from these transport cells and infect nerve cells directly or cause indirect damage to neurons by the release of cytokines such as tumor necrosis factor and interleukin-2. (Reprinted by permission from Ho D, Pomerantz RJ, Kaplan JC. Pathogenesis of infection with human immunodeficiency virus. *N Engl J Med* 1987;317:278-86.)

neurologic effects of HIV infection. In adults with progression of disease, depletion of $CD4^+$ cells has been linked to shifts in coreceptor use (from CXCR4 to CCR5), and these individuals with more severe disease appear to harbor predominantly CCR5-dependent (R5) viral strains.[99] HIV-containing monocytes are thought to transport HIV into the CNS and infect microglial cells including astrocytes.[56] Also implicated in HIV-associated neurologic complications are glial soluble factors that may have a direct neurotoxic effect.[149] Cytokines and reactive oxygen species released by HIV-infected lymphocytes and macrophages in the CNS may damage exposed nerve tissue.[268] The normal CNS immune defense system can attempt to enhance neuronal survival.

Origin of Immunodeficiency

The use of HAART has provided important opportunities to evaluate immune restoration in infected hosts. $CD4^+$ cell-depletion hypotheses of programmed cell death (apoptosis), depletion of tissue-associated $CD4^+CD45^+$ effector memory cells during acute infection, chronic ineffective immune activation (cellular and humoral), and switch from CXCR4-dependent virus (X4 virus) in acute infection to CCR5-dependent virus (R5 virus) in chronic infection all have been implicated as causes of HIV-induced immunodeficiency. In a recent study, using ligands to Toll-like receptors (TLRs) 5 and 9, the effect of TLRs on HIV-1 replication in lymphoid tissue was evaluated. Although flagellin (TLR5 agonist) treatment enhanced replication of CCR5-tropic and CXCR4-tropic HIV-1, treatment with oligodeoxynucleotide (ODN) M362 (TLR9 agonist) suppressed both viral variants. The differential effects of these TLR ligands on HIV-1 replication correlated with changes in production of CC chemokines CCL3, CCL4, CCL5 and of CXC chemokines CXCL10 and CXCL12 in the ligand-treated HIV-1–infected tissues.[20] These results suggest that a particular pattern recognition receptor engaged by a microbe may account for various microbial effects on HIV-1 replication in coinfected tissues and eventually affect the course of HIV-1 disease.

Ligands that induce apoptosis have been studied in HIV-infected individuals, and tumor necrosis factor–related apoptosis inducing ligand (TRAIL) has been documented to result in neuronal death.[178] TRAIL-associated apoptosis appears to require CXCR4 coreceptor expression but not CCR5 or CD4 receptor expression.[160]

Investigators hypothesize that HIV first depletes mucosal $CCR5^+CD4^+$ effector memory cells, thus leaving short-lived central memory or naïve $CD4^+$ cells and other immunoregulatory cells in a chronic state of activation that leads to an ineffective host response.[69,108] Infection of $CCR5^+CD4^+$ effector memory cells also is associated with higher expression of CTLA-4, a potent negative regulator for $CD4^+$ cells.[282] High expression of CTLA-4 may interrupt IL-2 production by $CD4^+$ cells, thereby impeding the ability of these cells to proliferate and hence depleting the population. The resultant chronic immune activation may lead to disorganization of the host immune response and further deplete $CD4^+$ cell regeneration. For patients with the most profound $CD4^+$ T-cell depletion, reduction of viral load with antiviral agents does not immediately result in correction of their immune defects.[99] The study of immune reconstitution with HAART may illuminate the immunopathogenesis of HIV infection. For example, after administration of HAART, $CD4^+$ NK T cells that play an important part in regulatory immune response to viral infections are restored rapidly. Restoration of such $CD4^+$ cell populations after administration of HAART and their important immune function may explain why, in the presence of persistently skewed $CD4^+$ cell expression in peripheral blood, clinical disease appears to improve dramatically.[205,264]

In perinatal HIV infection, the role of the placenta in affording protection or permitting infection continues to be defined, and potential perinatal cofactors are beginning to be understood more clearly. Thus, HIV may be fetotoxic, with an impact most notably reported in the thymus, where precocious involution, epithelial injury, and, occasionally, severe thymitis are described. Loss of lymphocytes at the corticomedullary junction of the thymus implies a defect induced by HIV in the immunologic selection process.

CLINICAL MANIFESTATIONS

In children and adults, HIV infection causes a spectrum of clinical abnormalities that affect multiple organ systems and include the symptom constellation of AIDS. Table 191B-4 lists the pre-HAART frequency of AIDS-defining events per 100 child-years.[181]

Infection with HIV, independent of a diagnosis of AIDS, may be attended by nonspecific clinical findings, including mild failure to thrive, hepatosplenomegaly,

acquired microcephaly, parotitis, generalized lymphadenopathy, nonspecific intermittent diarrhea, intermittent fever, and chronic skin disease. These clinical symptoms are shared by other pediatric disease processes and can, when manifested singly in an HIV-infected host, cause a delay in establishing the diagnosis. However, a careful and detailed history should provide helpful insight into potential HIV risk factors and should prompt inclusion of HIV infection in the differential diagnosis. With the use of HAART, HIV infection has become a chronic disease and new clinical disease manifestations (e.g., lipodystrophy, hyperlipidemia), most closely related to chronic antiviral use, have been described. In general, the health of HIV-infected children has improved during the past decade. Kourtis and associates reported a dramatic decrease (71%) in the number of hospitalizations among children with HIV infection who were 18 years and younger between 1994 (pre-HAART) and 2004 (post-HAART).[144]

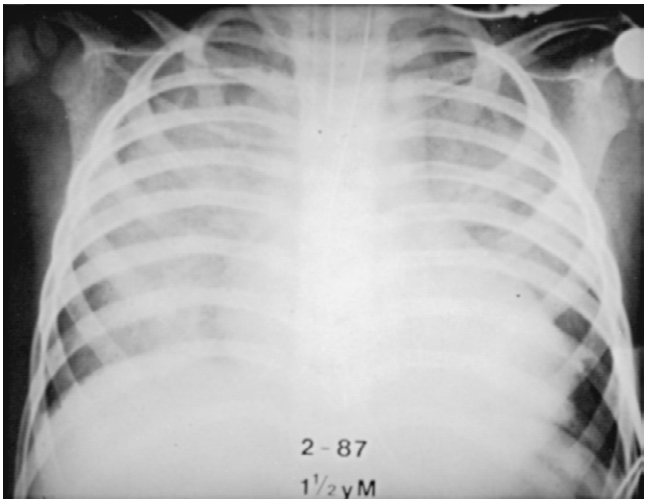

FIGURE 191B-4 ■ Classic diffuse interstitial infiltrates of acute and fatal pneumonia due to infection with *Pneumocystis jiroveci* in a 15-month-old child with perinatal acquired immunodeficiency syndrome. (From Hanson IC. Respiratory infections in HIV-infected children. Immunol Allergy Clin North Am 1993;13:205-17.)

Opportunistic Infections

Opportunistic infections plague HIV-infected individuals and are the most prominent cause of morbidity and mortality in this cohort. Before the use of HAART intervention, opportunistic infections in children more often were primary infections as compared with the case in adults, who had reactivation of infection.[181] The introduction of effective HAART with associated host immune restoration significantly modified the expression of certain opportunistic infections in adults and children.[252] In children, the overall incidence of these infections declined from 14.4 cases per 100 patient-years before 1997 to 1.1 cases per 100 patient-years.[190] Additionally, in pre-HAART years, the age at clinical presentation was much younger and age younger than 3 years was associated with very rapid $CD4^+$ cell decline. Although the number of these opportunistic diseases has diminished, their prevalence appears to be unaffected. The administration of combination HIV therapy, including protease inhibitors (PIs) in adults and children, has improved the survival of perinatally infected children.[100]

Pneumocystis Pneumonia

P. jiroveci (formerly *P. carinii*) pneumonia (PCP) is the opportunistic infection most commonly reported in HIV-infected children. Declines in the incidence of PCP have been documented, with rates of 5.8 cases per 100 patient-years reported before 1997 and 0.3 cases per 100 patient-years reported after 1997.[190] PCP has a fulminant course in the pediatric population, with the highest mortality rates occurring in affected children younger than 1 year old. In a study of 172 children with perinatal HIV infection without HIV-specific intervention, 9 percent had PCP when they were younger than 1 year, with a median survival of 1 month. Clinical expression of pediatric PCP often can be distinguished from other pulmonary diseases by the severity of the hypoxemia (higher alveolar-arterial oxygen gradients), elevated serum lactate dehydrogenase levels, the rapidity of progression of disease with tachypnea and fever, characteristic diffuse interstitial infiltrates on radiography, and the usual lack of digital clubbing.[113] The more insidious manifestations of PCP characteristic of HIV-infected adults, namely, prolonged fever (>7 weeks), cough, and dyspnea (averaging 3 weeks), are appreciated less commonly in infants and children. Radiographically, pediatric PCP is associated with diffuse interstitial markings progressing to the "white out" picture of adult respiratory distress syndrome (Fig. 191B-4).[114] However, PCP can be seen initially as a unilateral streaky pneumonic infiltrate, as lobar consolidation, or with accompanying pleural effusions.

Aggressive diagnostic measures may be indicated to establish a diagnosis of PCP. Bronchoscopic alveolar lavage (BAL) is the preferred diagnostic tool in adults and children and should be considered a first choice for presumed PCP in children who cannot provide sputum specimens for evaluation. In older children and adults, evaluation of sputum for the presence of *Pneumocystis* with appropriate stains or monoclonal antibodies may preempt the need for using invasive diagnostic measures. Polymerase chain reaction (PCR) assays have also been developed for diagnostic evaluation of PCP that are usually more sensitive but less specific than microscopic methods.[121] Lung biopsy carries the highest sensitivity for identifying the organism but has attendant morbidity related to thoracotomy or video-assisted thoracoscopy (VATS) and placement of a chest tube.

Acute PCP is treated with parenteral trimethoprim-sulfamethoxazole (TMP-SMX) or pentamidine or atovaquone for patients with TMP-SMX or pentamidine hypersensitivity. TMP-SMX treatment consists of 15 to 20 mg/kg/day of the TMP component delivered intravenously three to four times daily. Adjunctive corticosteroid therapy given early in moderate to severe PCP provides significant benefit with only limited evidence of concomitant immune suppression and attendant infectious complications.[91,242] Concomitant CMV and PCP has been documented in HIV-infected children. In this clinical

TABLE 191B-5 Recommendations for *Pneumocystis* Pneumonia Prophylaxis and CD4⁺ Monitoring for Infants Exposed to and Children Infected with HIV by Age and HIV Infection Status

Age/HIV Infection Status	Prophylaxis	CD4⁺ Monitoring
Birth to 4-6 wk, HIV exposed	No prophylaxis	
4-6 wk to 12 mo, HIV exposed	No prophylaxis*	
<12 mo, HIV infected or indeterminate	Prophylaxis	Every 3-4 mo
1-5 yr, HIV infected	Prophylaxis *if* CD4⁺ count is <500 cells/μL or CD4⁺ percentage is <15%	Every 3-4 mo
6-12 yr, HIV infected	Prophylaxis *if* CD4⁺ count is <200 cells/μL or CD4⁺ percentage is <15%	Every 3-4 mo

*Until HIV infection is either presumptively excluded (by documentation of two negative virologic test results, one at ≥2 wk of age and one at ≥4 wk of age) or definitively excluded (by documentation of two negative virologic test results, one at ≥1 mo of age and one at ≥4 mo of age). For these definitions of HIV exclusion to be valid, the infant must not be breast-feeding.

Modified from Mofenson LM, Brady MT, Danner SP, et al. Guidelines for the prevention and treatment of opportunistic infections among HIV-exposed and HIV-infected children: recommendations from CDC, the National Institutes of Health, the HIV Medicine Association of the Infectious Diseases Society of America, the Pediatric Infectious Diseases Society, and the American Academy of Pediatrics. *MMWR Recomm Rep* 2009;***58***(RR-11):1-166.

situation of concomitant viral infection, no existing data recommend delay of corticosteroid use. Treatment of PCP should not be altered. Dosing regimens for corticosteroids are published and include options for use of oral prednisone or oral methylprednisolone or intravenous methylprednisolone.[39]

Following the occurrence of PCP infection, secondary PCP prophylaxis (therapy initiated after acute disease treatment and resolution) is recommended (see Table 191B-5). Proposed pediatric regimens include TMP-SMX at 150 mg/m²/day and 750 mg/m²/day, respectively, in two divided doses on 3 consecutive days/week (acceptable alternate regimens include a single dose on 3 consecutive days/week, two divided doses on 3 alternate days a week, two divided doses daily), dapsone for children 1 month or older at 2 mg/kg daily (single dosing not to exceed 100 mg/day) or 4 mg/kg weekly (single dosing not to exceed 200 mg), for children 5 years or older, pentamidine (aerosolized [300 mg by Respirgard II inhaler monthly]), and atovaquone (30 mg/kg daily for children 1 to 3 months and >24 months and 45 mg/kg daily for children 4 to 24 months).[180] In adults and adolescents, recommendations to discontinue secondary PCP prophylaxis are proposed once there is documentation of immune restoration (CD4⁺ cell counts that have increased to >200 cells/mm³ for ≥3 months as a result of HAART).[39] Data from the European PCP-Withdrawal Study Group suggest that with immunorestoration of HAART the risk for PCP development is low and that withdrawal of PCP prophylaxis as recommended in the adult host appears to be a reasonable risk.[263] U.S. guidelines continue to recommend lifelong primary PCP prophylaxis in individuals who acquired their PCP before reaching 13 years of age.[181]

Primary PCP prophylaxis (therapy initiated to prevent primary infection) for adults and children is accepted as standard care.[39] Pediatric regimens and dosing for secondary PCP prophylaxis do not differ from those outlined earlier. In 1993, the CDC published the first PCP prophylaxis guidelines for HIV-infected children; these guidelines linked the institution of therapy to the level of immunosuppression as measured by the CD4⁺ cell count or percentage.[34] Guidelines for PCP prophylaxis were modified in 2009.[180] The most significant change in the revised guidelines was concerning diagnosis of HIV infection and presumptively excluding HIV infection in infants that affect the need for initiation of prophylaxis to prevent PCP in neonates. Based on this revision, prophylaxis is not recommended for infants who meet criteria for being definitively or presumptively not HIV infected. In non–breast-feeding infants with no positive HIV virologic test results, presumptive exclusion of HIV infection can be based on two negative virologic test results (one obtained at 2 weeks or older and one obtained at 4 weeks of age), on one negative virologic test result obtained at 8 weeks of age or older, or on one negative HIV-antibody test result obtained at 6 months of age or older. Definitive exclusion of HIV infection is based on two negative virologic test results (one obtained at 1 month of age or older and one obtained at 4 months of age or older) or on two negative HIV-antibody test results from separate specimens obtained at 6 months of age or older. For both presumptive and definitive exclusion of infection, the child should have no other laboratory or clinical evidence of HIV infection. Infants born to HIV-infected mothers should be considered for prophylaxis beginning at 4 to 6 weeks of age. HIV-infected infants should be administered prophylaxis until 1 year of age, at which time they should be reassessed on the basis of the age-specific CD4⁺ T-cell count or percentage thresholds. Infants with indeterminate HIV infection status should receive prophylaxis until they are determined to be HIV-uninfected or presumptively uninfected with HIV. Data from Pediatric AIDS Clinical Trials Group protocol 1088 documented that primary PCP prophylaxis in HIV-infected children could be discontinued safely with immune restoration on stable antiretroviral therapy.[189]

Infection with *Mycobacterium avium–intracellulare* Complex

The *M. avium–intracellulare* complex (MAC), which caused disseminated infections in both adults and children with HIV infection in the early 1980s and 1990s, waned significantly in incidence with the increasing and

successful use of HAART. In a 1990 review of opportunistic infections in pediatric patients with AIDS, 43 of 552 (7.8 percent) children from birth to 9 years of age were found to have disseminated MAC infection.[113] The incidence of pediatric MAC infection in HIV-infected children dropped from 1.3 cases per 100 patient-years reported before 1997 to 0.2 cases per 100 patient-years after 1997.[190] Epidemiologically, MAC has been linked to significant immunosuppression ($CD4^+$ T cell counts lower than 50 cells/mm^3) in adults.[39,182] Researchers noted that the development of MAC infection in children may be associated with $CD4^+$ T cell counts greater than 50 cells/mm^3, especially in children younger than 6 years old.[222] Symptoms of MAC infection include fever, malaise, weight loss, anorexia, and night sweats. Gastrointestinal manifestations are not uncommon and have included abdominal pain, diarrhea, malabsorption, and intestinal perforation. Rarely, MAC has been reported with extrabiliary obstructive jaundice (presumed to be secondary to lymphadenopathy) and endobronchial masses. The diagnosis of disseminated MAC infection relies on identification of these microorganisms from the blood, lymph tissue, bone marrow, liver, lungs, and gastrointestinal tract. Therapy for disseminated MAC infection in the pediatric population includes some combination of clarithromycin or azithromycin (maximal dosing of 500 mg and 250 mg, respectively) and/or rifabutin (maximal dosing of 300 mg). The epidemiologic link with severe immunosuppression and the advent of therapeutic prophylactic interventions (clarithromycin or azithromycin and/or rifabutin) prompted the implementation of MAC prophylaxis guidelines for adults, adolescents, and older children (≥6 years) with $CD4^+$ T cell counts lower than 50 cells/mm^3.[35] Primary MAC prophylaxis can be discontinued in HIV-infected children older than 2 years of age receiving stable HAART for 6 months or more and sustaining (>3 months) $CD4^+$ T cell recovery.[189]

An unusual immune restoration inflammatory syndrome (IRIS) has been described as a paradoxical event after immune recovery has been achieved in adults and adolescents receiving HAART.[248] IRIS is associated with reactivation of opportunistic infections such as MAC. Activation of other latent complications, including carcinoma and neurologic symptoms, has been described.[261] Recent data indicate that MAC prophylaxis with azithromycin did not prevent IRIS.[203] In children with IRIS, treatment of the reactivated opportunistic infection may include administration of anti-inflammatory agents including systemic corticosteroids.

Tuberculosis

Overall case rates of tuberculosis (TB) in the United States are declining, with 4.4 new cases of TB per 100,000 population (a total of 13,299 cases) reported in 2007. The percentage of patients with TB and with known HIV infection also decreased from 15.0 percent in 2003 to 12.4 percent in 2006.[43] Primary disease accounts for one third or more of cases of TB in HIV-infected populations.[277] In a cohort of pregnant and nonpregnant HIV-infected women monitored in a multicenter longitudinal study, the prevalence of tuberculosis determined by medical history or positive skin tests was 14 percent.[181] Children most commonly are infected with *Mycobacterium tuberculosis* from exposure in their immediate environment, usually the household. In a study of 60 HIV-infected families, the incidence of tuberculosis was approximately 6 percent, with both HIV-infected and HIV-uninfected children affected. The vector for transmission was identified as an infected family member or caregiver.[9] Tuberculosis should be considered in the differential diagnosis of pulmonary disease in HIV-exposed children. The principles for treating TB in the HIV-infected child are the same as for the HIV-uninfected child and should include at least a four-drug regimen. However, treating TB in an HIV-infected child is complicated by antiretroviral drug interactions with the rifamycins and overlapping toxicities caused by antiretroviral agents and TB medications. The duration of treatment is 9 to 12 months, with the longest duration being in children with extrapulmonary disease.[38]

Secondary prophylaxis is not recommended for children who have had a prior episode of TB.

Cytomegalovirus

In the pre-antiretroviral era, CMV caused 8 to 10 percent of pediatric AIDS-defining illness.[136] The adult spectrum of CMV disease, including retinitis, pneumonitis, esophagitis, gastritis, colitis, hepatitis, cholangitis, and encephalitis, is not reported uniformly in the pediatric AIDS literature. CMV clearly can cause primary pneumonitis in children or can be found in association with other pulmonary pathogens, especially *Pneumocystis*. Unusual gastrointestinal manifestations have included pyloric obstruction, enterocolitis, and oral and esophageal ulcers. CMV retinitis is the most frequent severe manifestation of CMV disease among HIV-infected children, accounting for approximately 25 percent of CMV AIDS-defining illnesses.[52] However, it appears to be decreasing in incidence with the wider use of HAART.[190] Annual CMV antibody testing is recommended beginning at 1 year of age for CMV-seronegative HIV-infected infants and children who are severely immunosuppressed.

Treatment of CMV disease-associated with HIV infection focuses on progression of disease and not on a curative outcome. Therapeutic intervention includes the use of ganciclovir, valganciclovir, foscarnet, or cidofovir. These drugs have significant side effects, including bone marrow suppression and renal toxicity. Administration of these agents is divided into induction and maintenance dosing. The optimal interval for efficacy has not been determined and often is selected on an individual basis. Although many adults report experiencing subjective and objective improvement while receiving therapy, discontinuation of therapy is associated with high relapse rates, independent of the affected site. Careful monitoring of children receiving treatment for CMV and antiretroviral therapy is imperative because the use of both classes of agents may depress bone marrow function. CMV end-organ disease is best prevented by antiretroviral therapy to maintain CD4 count greater than 100 cells/mm^3. If this is not possible, prophylaxis with valganciclovir can be considered for HIV-infected older children who are

CMV seropositive, with severe immune suppression ($CD4^+$ T cell count <50 cells/mm^3), at a dose of 15 mg/kg/dose every 12 hours, using a 50-mg/mL pediatric solution that is now available, or using tablets if the child weighs enough to receive adult doses of valganciclovir. Prevention of complications of CMV in HIV-infected children with severe immunosuppression should include careful and regular (every 4 to 6 months) retinal monitoring for evidence of eye disease. Once secondary prophylaxis for disseminated CMV disease is initiated, its discontinuation should be considered on a case-by-case basis because current data to support discontinuation are limited.[272] As reported with MAC, reactivation of CMV disease in the IRIS has been described.

Other Herpesvirus Infections

Infections with the herpesvirus family are not uncommon events in HIV-infected children. In a study in the United States during the HAART era, the incidence of systemic HSV infection was 0.9 per 100 child-years and was most common among children with reduced CD4 percentage (<25%).[98] In general, HSV infection in pediatric AIDS has been limited to mild to severe localized infections without reports of dissemination. Varicella-zoster virus (VZV) and herpes-zoster virus (HZV) infections have contributed significant morbidity to HIV-infected persons. Disseminated and chronic HZV infections are reported in pediatric patients with AIDS. Because episodes of HSV disease can be treated successfully, chronic therapy with acyclovir is not required after lesions resolve. However, children who have frequent or severe recurrences can be administered daily suppressive therapy with oral acyclovir.[77] Prevention of herpes infections in school-aged children is especially important because exposure to varicella may be considerable. Administering varicella-zoster immune globulin, if available, should be considered for susceptible HIV-infected children with exposure to VZV. Because the varicella vaccine is an attenuated live viral vaccine, its use in HIV-infected children is limited currently to children with asymptomatic or mildly symptomatic HIV disease and no evidence of immune suppression.[42]

Fungal Diseases

The most common fungal infections among HIV-infected children are caused by *Candida* spp. Oral thrush and diaper dermatitis occur among 50 to 85 percent of HIV-infected children.[98] Affected mucous membranes or skin often does not respond well to treatment with topical antifungal agents. Systemic therapy with one of the oral azoles including fluconazole, ketoconazole, or itraconazole is effective in oropharyngeal or esophageal candidiasis. In severe fungal infections, amphotericin B or other agents effective against the *Candida* spp. should be administered intravenously. Because of limited experience in children and no data in HIV-infected children, data are insufficient to recommend echinocandin class antifungal medications, including caspofungin, micafungin, and anidulafungin, as first-line agents for invasive candidiasis in children.[233] Prophylaxis for candidal infections is not recommended because of concern for development of resistance to azoles such as fluconazole, which could limit the use of these agents in the care of disseminated or mucosal disease.[39]

Other disseminated fungal diseases, such as histoplasmosis and cryptococcosis, less commonly affect pediatric patients with AIDS. Histoplasmosis may be prevalent in HIV-infected children who reside in parts of the United States where *Histoplasma capsulatum* is endemic. Symptoms of histoplasmosis include fever, rash, cough, lymphadenopathy, splenomegaly, thrombocytopenia, low-grade disseminated intravascular coagulopathy, adult respiratory distress syndrome, meningoencephalitis, and neurologic abnormalities consistent with intracranial mass lesions. Symptoms of cryptococcosis include fever, headache, pulmonary involvement, and subacute meningitis or meningoencephalitis.[177] Because of the low incidence of histoplasmosis in pediatric HIV-infected patients, possibility of drug interactions, potential antifungal drug resistance, and cost, the routine use of antifungal medications for primary prophylaxis of *Histoplasma* infections in children is not recommended. However, primary prophylaxis for adults and adolescents is suggested for those with compromised immune systems. Specifically, fluconazole is suggested as primary cryptococcosis prophylaxis for adults and adolescents with $CD4^+$ T cell counts of less than 50 cells/mm^3 and itraconazole is advised for histoplasmosis prophylaxis in adults and adolescents with $CD4^+$ cell counts of less than 150 cells/mm^3. The safety of discontinuing secondary prophylaxis for cryptococcosis after immune reconstitution with HAART has not been studied in children, and decisions in this regard should be made on a case-by-case basis. Recommendations to discontinue prophylaxis as a result of HAART-related improved immune function have been developed for cryptococcosis and include sustained (>6 months) $CD4^+$ T cell counts higher than 200 cells/mm^3.[134] In contrast, no such recommendations exist for discontinuation of histoplasmosis prophylaxis in HIV-infected adults or adolescents with evidence of HAART-related reconstitution of immunity.

Bacterial Diseases

Pediatric patients have an increased incidence of severe bacterial infections, including infections with *Streptococcus pneumoniae*, *Staphylococcus aureus*, and various gram-negative organisms. One of the most common first-time infections in HIV-infected children is bacterial infections (bacterial pneumonia).[98] In a study of 372 HIV-infected children monitored for a median of 17 months, 14 percent experienced one or more laboratory-proven serious bacterial infections. More recent findings suggested that the incidence of bacterial disease dropped from rates of 4.7 cases per 100 patient-years before 1997 to 0.2 cases per 100 patient-years after 1997 (HAART era).[190] Reported clinical infections included bacteremia, pneumonia, osteomyelitis, meningitis, and sinusitis. Therapy is directed against the specific isolated bacterial pathogen, and the dosing and duration of therapy depend on the affected site. Prophylaxis against bacterial infections initially should include vaccination with appropriate

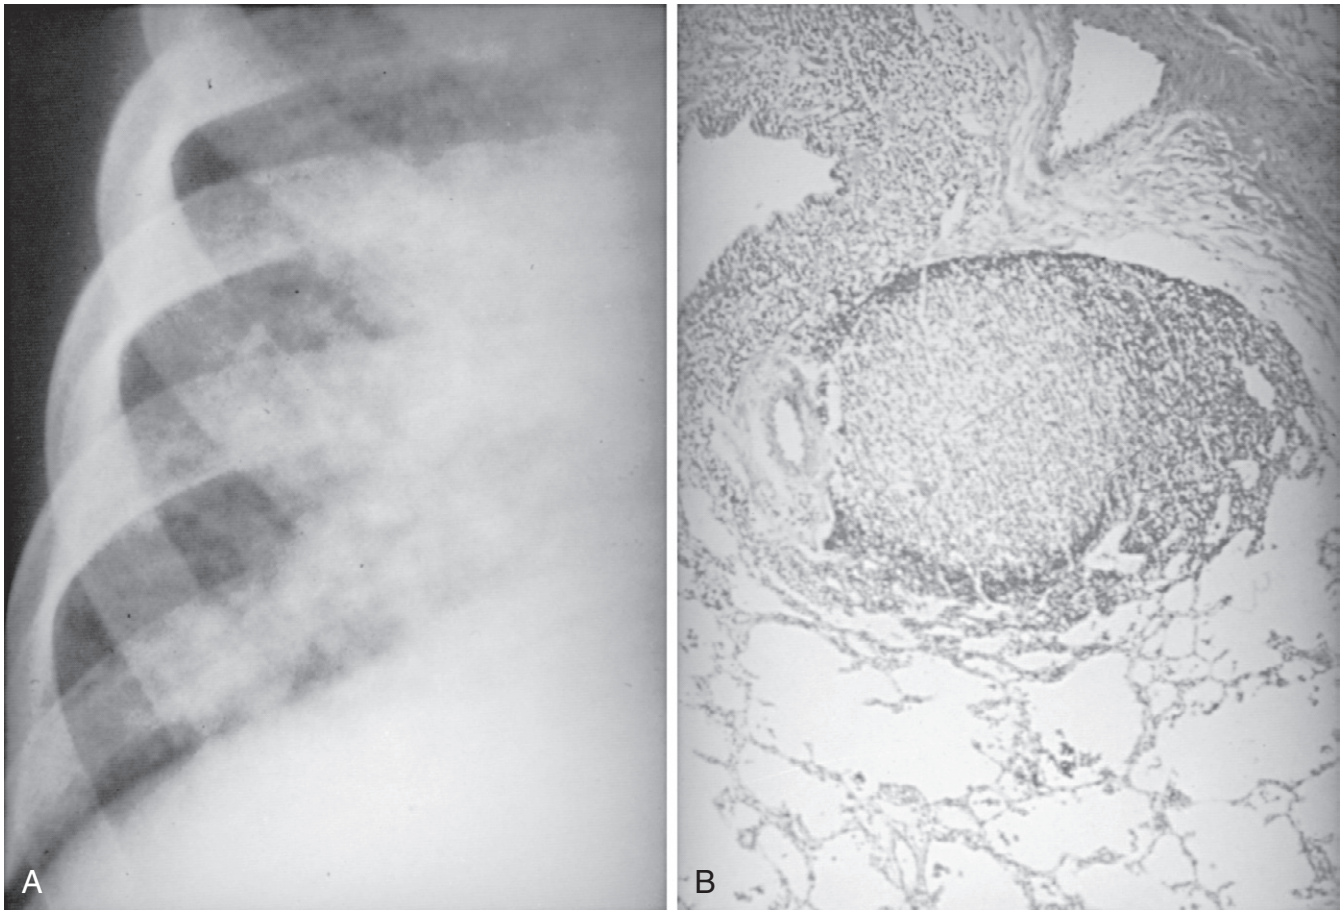

FIGURE 191B-5 ■ **A,** Chest radiograph documenting parenchymal nodularity in a 3-year-old child with perinatal AIDS. **B,** Pulmonary lymphoid hyperplasia in the child showing histologic changes, including interstitial widening and prominent peribronchial lung nodes.

childhood vaccines, including *Haemophilus influenzae* type b, pneumococcal conjugate vaccines, meningococcal conjugate vaccines, and inflluenza.[193] Other medications available for bacterial prophylaxis include intravenous immune globulin (IVIG), TMP-SMX, atovaquone, and azithromycin. Of note, IVIG is no longer recommended for primary prevention of serious bacterial infections in HIV-infected children unless hypogammaglobulinemia is present or functional antibody deficiency is demonstrated.

COMPLICATIONS

Pulmonary Complications

In addition to PCP and chronic sinopulmonary infection, noninfectious pulmonary complications of pediatric AIDS are associated with morbidity. Chronic lung disease is common in HIV-infected children with increasing age. A longitudinal birth cohort study reported a cumulative incidence of chronic radiographic lung changes in HIV-infected children of 33 percent by 4 years of age.[192] The spectrum of chronic HIV-associated lung disease includes lymphocytic interstitial pneumonia (LIP)/pulmonary lymphoid hyperplasia (PLH), chronic infections, IRIS, bronchiectasis, and malignancies.[281] Lymphoid interstitial pneumonitis and *P. jiroveci* pneumonitis have largely disappeared in developed countries but remain a significant problem in developing countries.[281] The incidence of *P. jiroveci* pneumonitis (previously 1.3 per 100 child-years) is now 0.13 per 100 child-years. LIP is similarly affected by HAART. Bacterial pneumonia remains relatively high (2.2 per child 100 years) although markedly reduced from the time period prior to HAART when the incidence was fivefold higher.[281] Bronchiectasis may reappear as a serious complication of HIV infection if chronic inflammation of the lung (generally controlled by HAART therapy) takes its toll over the years, given that the oldest surviving HIV-infected children are now approaching 30 years of age.

Histopathologically, LIP and PLH appear to be distinct entities, although whether these disorders represent a continuum of reactive hyperplasia of lymphoid tissue is somewhat controversial. In LIP, small lymphoid infiltrates are dispersed throughout parenchymal lung tissue and often are accompanied by alveolar epithelial hyperplasia and interstitial widening. PLH describes larger, dense nodular aggregates of lymphoid tissue both in distal parenchymal tissue and in the walls of bronchi and bronchioles (Fig. 191B-5A). Compression of blood and lymphatic vessels by these nodules may contribute to the

accompanying clinical interstitial widening. The cause of LIP/PLH has not been defined. Simultaneous infection with EBV and HIV may amplify the risk for development of LIP. B lymphocytes infected with EBV are very susceptible to HIV infection in vitro and could enhance intrapulmonary replication of HIV.[259] Clinically, LIP/PLH is characterized by a nonproductive cough and the insidious onset of progressive hypoxia. The hypoxemia may be subtle and best appreciated during febrile, upper respiratory tract illnesses. Digital clubbing, generalized lymphadenopathy, chronic parotitis, or failure to thrive may accompany LIP/PLH[201,253] Radiographically, LIP/PLH often demonstrates characteristic interstitial infiltrates with a nodular pattern (see Fig. 191B-5B). This radiographic picture frequently mimics that of miliary tuberculosis and warrants exclusion of this pulmonary infection. In an immunocompromised, anergic, HIV-positive child, simple delayed hypersensitivity skin testing for exclusion of tuberculosis may not suffice and BAL or gastric aspiration for detection of acid-fast microorganisms may be necessary. Lung biopsy is the definitive diagnostic procedure for LIP/PLH. However, in HIV-infected children, a presumed diagnosis of LIP/PLH by the less invasive exclusion of infectious pathogens is preferred.

Therapy for LIP/PLH is not defined clearly because the clinical outcome is variable. HIV-infected children with LIP/PLH have been noted to have spontaneous remissions without therapeutic intervention, whereas other affected children progress to respiratory insufficiency and failure. Therapeutic interventions have included IVIG supplementation, antiretroviral therapy, corticosteroids (daily or alternate-day dosing ranging from 0.5 to 2.0 mg/kg/day), and observation. No significant associated infectious sequelae (bacteremia, fungemia) of corticosteroid use were reported in treated children. Supportive therapy consisting of oxygen supplementation, chest physical therapy, and attention given to adequate nutritional intake is helpful.[103,201]

Other noninfectious pulmonary complications have been reported less frequently in the pediatric HIV-infected population. Evidence of an increased incidence of asthma in HIV-infected children, adolescents, and young adults has been shown in a series of peer-reviewed publications.[86-88,111,238] In the most recent of these, both physician-diagnosed asthma and asthma medication use demonstrated at least a 30 percent increase in the incidence of asthma (HIV-infected vs. HIV-exposed but not infected patients) and offered compelling evidence that more than one manifestation of allergic disease appeared in these patients.[238] Atopic dermatitis was also increased in HIV-infected patients and appeared shortly after birth and before the asthmatic child was diagnosed, very much resembling the order that appears in the general pediatric population.

So far, two potential mechanisms have been discovered that may underlie the increased incidence of asthma in HIV-infected youth. The first of these is genetic inheritance of human leukocyte antigens (HLA)-class I genes that are associated with new disease appearance after patients with HIV infection are immune reconstituted with HAART.[86] The second mechanism that may be applicable to the appearance of new disease in immunoreconstituted patients infected with HIV is a sudden return of cellular immunity (as measured by $CD4^+$ T-cell increases) that may precipitate a dysregulated attack on HIV in the airways, as well as commensal fungi that colonize and/or infect the airways of HIV-infected patients.[13] In experimental animal models, this sudden burst of immune stimulation precipitates an asthma attack.[209,210]

Central Nervous System Complications

Neurologic abnormalities have been documented in persons with HIV and can be attributed to opportunistic infections, adverse events of primary treatment, or primary infection with HIV, especially in light of HIV's described tropism for monocytes. Diverse neurologic and neurobehavioral deficits are common in children with HIV-1 infection and include abnormal neurologic examinations (e.g., global pyramidal tract signs, hemiparesis, peripheral neuropathy, visual, and hearing impairment), neurobehavioral problems, encephalopathy, and epilepsy.[11,101,129] Children with severe immunosuppression, with immune activation not receiving antiretroviral therapy, and who are growth impaired and younger than 1 year of age are at greatest risk for developing neurologic complications.[148,172] In 1994, the definition of HIV encephalopathy was adapted directly to children as a criteria for the diagnosis of AIDS and consists of at least one of the following features present for at least 2 months: (1) failure to attain or loss of developmental milestones or loss of intellectual ability, verified by a standard developmental scale or neuropsychological tests; (2) impaired brain growth or acquired microcephaly demonstrated by head circumference measurements or brain atrophy identified by computed tomography (CT) or magnetic resonance imaging (MRI) (serial imaging is required for children younger than 2 years old); and (3) acquired symmetric motor deficit manifested by two or more of the following: paresis, pathologic reflexes, ataxia, or gait disturbance.[36]

The precise pathogenesis of the encephalopathic changes associated with HIV infection remains elusive, although cellular tropism of HIV has been implicated.[143] Histopathologically, most children with involvement of the CNS show significant brain atrophy. Inflammatory lesions usually are sparse and alone cannot account for the significant amount of atrophy observed. Other purported factors potentially contributing to diminished brain size have included the following: (1) direct or indirect interference of HIV with brain growth (HIV toxic effect versus competition with brain growth factors such as neuroleukin), (2) severe malnutrition, (3) severe hypoxia from cardiac and pulmonary compromise, and (4) therapeutic regimens for infectious or noninfectious processes that mandate the prolonged use of medications that may inhibit brain growth.[157,231] A prospective study of a cohort of 319 perinatally HIV-infected children aged 6 to 17 years observed over a 2-year period indicated associations of past and current CDC class C designation with less severe attention-deficit/hyperactivity disorder inattention symptoms, older age at nadir $CD4^+$ T cell percentage and lower $CD4^+$ T cell percentage at study

entry with more severe conduct disorder symptoms, higher RNA viral load at study entry with more severe depression symptoms, and lower $CD4^+$ T cell percentage at study entry with less severe symptoms of depression. There was little evidence of an association between specific antiretroviral therapy and severity of psychiatric symptoms. A lower nadir $CD4^+$ T cell percentage was associated with lower quality of life, worse Wechsler Intelligence Scale for Children Coding Recall scores, and worse social functioning.[188] In a cohort of perinatally HIV-infected children with severe disease, Kapetanovic and colleagues concluded that higher $CD4^+CD38^+HLADR^+$ percentage may be associated with a neuroprotective effect and higher percentage of $CD4^+CD38^+$ but $HLADR^-$ T cells may be deleterious.[130] Attention-deficit hyperactivity disorder, learning disability, and graphomotor weakness have been described in higher proportions in HIV-infected children with transfusion-acquired infection.

Behavioral, neurodevelopmental, and, occasionally, imaging improvements have been documented with nucleoside inhibitor intervention. In a study of 146 perinatally HIV-infected children born between 1990 and 2003, the prevalence of encephalopathy (progressive or static) decreased from 40.7 percent before 1996 (limited combination antiviral therapy) to 18.2 percent after that year.[234] In this cohort, neurocognitive scores remained stable over the course of a 6-month period in children receiving combined antiviral therapy and only a weak association with lowered viral load could be found. Clearly, antiviral therapy not only must achieve effective serum and plasma concentrations but also must be able to cross the blood-brain barrier and affect HIV-infected CNS monocytes. On the contrary, the results of a longitudinal cohort study involving HIV-infected and HIV-exposed but uninfected infants and children reported effects of PI-based HAART showing a positive but limited impact on neurodevelopmental trajectories and the rate of significant cognitive and motor impairment in HIV-infected infants and young children during the first 3 years of life.[156] In this study, infants with immune suppression ($CD4^+$ T cell percentages <25%) seemed to be most vulnerable with respect to neurodevelopmental functioning, demonstrating mental and motor scores lower than those of the HIV-negative infants, as well as HIV-infected infants with less immune suppression.

Sleep disturbances, neurocognitive deficits, and abnormal psychosocial function are associated with abnormal cytokine levels in children with HIV infection.[17,195,229,276] A National Heart, Lung and Blood Institute (NHLBI)–funded study attempted to discern a molecular pathway of these complications of pediatric HIV infection by assessing proinflammatory cytokine production in $CD4^+$ and $CD8^+$ T-cells, disturbed sleep patterns, and results of neurodevelopmental testing in HIV-infected versus HIV-exposed children.[85] Compared with HIV-exposed children, there were significant associations in HIV-infected children between changes in intracellular proinflammatory cytokines (TNF-α, IFN-γ, IL-12), sleep patterns (particularly increased daytime sleep), and lower neurocognitive scores on socioemotional, behavioral, and executive function: working memory and mental fatigue; verbal memory; and sustained concentrations and vigilance. The authors of this sleep study in HIV-infected children proposed that therapies that reduced immune-mediated inflammation and prescribed sleeping habits might improve the neurocognitive and psychosocial problems.[85]

Children with neurologic or behavioral deficits and HIV infection should be evaluated by a pediatric neurologist, and developmental, audiologic, and ophthalmologic assessments are warranted. These children may need support systems including physical therapy, medications to assist with seizure control or contractures, specialized equipment (e.g., braces, splints, wheelchairs), and, as needed, medications or devices to assist with swallowing or food ingestion.

In pediatric AIDS, bacterial pathogens predominate as the most common cause of meningitis.[193] HIV rarely is isolated from cerebrospinal fluid. Other pathogens reported in the pediatric HIV-infected population include *Candida* spp., CMV, *M. tuberculosis*, *Toxoplasma*, and *Cryptococcus*. In the reported adult cases of IRIS-associated progressive multifocal leukoencephalopathy, brain biopsy lesions reveal severe demyelination and perivascular inflammatory response of monocytes and T lymphocytes.[105]

Gastrointestinal Complications

Gastrointestinal complications of HIV disease are encountered frequently in both children and adults. Before HAART, malnutrition was one of the most frequent and devastating complications of pediatric HIV, and it predicted both morbidity and mortality. Malnutrition in HIV-infected children has several causes, including reduced oral intake (HIV-induced primary cachexia, opportunistic infections of the upper gastrointestinal tract, and medication side effects), malabsorption (HIV alone or infections of the gastrointestinal tract), altered metabolic states (proinflammatory effects of chronic HIV infection), and socioeconomic factors.[174] Wasting has been revised from the 1987 definition to its present definition (1994): (1) persistent weight loss greater than 10 percent of baseline, (2) downward crossing of at least two of the percentile lines on the weight-for-age chart in a child 1 year or older, or (3) less than the 5th percentile on a weight-for-height chart on two consecutive measurements at least 30 days apart, plus (a) chronic diarrhea (at least two loose stools per day for ≥30 days) or (b) documented fever (≥30 days, intermittent or constant).[36] Although the prevalence of AIDS-associated wasting has declined in the developed world because of HAART, it is still a concern for children in both rich and poor nations. HIV and its complications also have been associated with specific nutritional disorders. Higher HIV viral load, lower $CD4^+$ T-lymphocyte counts, infections, maternal drug use, and zidovudine have been associated with growth problems.[176] The intestine is a primary target organ for HIV and also is important in the pathogenesis of HIV infection. In untreated HIV-infected children, as many as 80 percent will have one or more intestinal abnormalities at a given time. The pattern of intestinal dysfunction may change with time and can

occur without evident cause or change in clinical HIV stage or immunologic status.[65,109] The transactivator transfer factor, Tat, may be involved in intestinal dysfunction (HIV enteropathy) because it can impair enterocyte proliferation by targeting its L-type calcium sodium-glucose symporter. This pathway may explain many features of intestinal dysfunction, such as intestinal atrophy, carbohydrate malabsorption, and diarrhea, that are frequently observed.[65] Associated protein and micronutrient (zinc, selenium) deficiencies have been documented in HIV-infected adults and children.[51] Despite use of HAART, gastrointestinal conditions, nutritional deficiencies, and fluid and electrolyte disorders continue to be the most frequently described diagnoses for hospitalized HIV-infected children.[147]

More widespread use of maternal antiretroviral therapy to prevent HIV transmission has resulted in a decline in the percentage of HIV-exposed infants with low birth weight.[230] A study of more than 11,000 HIV-exposed or infected infants observed between 1989 and 2004 showed a 14 percent decline in low birth weight, from 35 to 21 percent, and this decline occurred independent of race or ethnicity. In contrast, growth and metabolic abnormalities persist in HIV-infected children either as a direct consequence of HIV infection or as an adverse outcome of antiviral therapy. Wasting and weight loss in HIV-infected individuals appear to be independent predictors of mortality and are associated with lower $CD4^+$ cell counts.[81,164] These studies have prompted careful attention to the nutritional needs of HIV-infected children. Specialized nutritional supplements such as nucleotides, polyamines, probiotics, and zinc can improve gastrointestinal absorption. Zinc may control diarrhea in HIV-infected children because it specifically counteracts Tat-induced intestinal ion secretion.[32] The polyamines, such as spermine, spermidine, and putrescine, can modulate intestinal maturation. Probiotics, including *Saccharomyces boulardii*, target the gastrointestinal tract and have antioxidant, antibacterial, enzymatic, anti-infective, metabolic, and anti-inflammatory activity. However, their effectiveness is not well established.[71,94]

The use of more potent antiretroviral therapy regimens, particularly those including PIs, has resulted in unwanted biochemical lipid abnormalities and changes in body composition for some HIV-infected adults and children. In a 2004 study of 94 infected children receiving long-term PI-containing antiviral regimens, 10 percent developed redistribution of fat, 52 percent developed dyslipidemia without associated somatic changes, and 38 percent had no associated findings.[255] In this cohort, changes in redistribution of fat and dyslipidemia were most likely to occur near ages consistent with the start of puberty (10 to 15 years). In a multicenter U.S. Perinatal AIDS Collaboration Transmission Study, 178 HIV-infected children were evaluated for hypercholesterolemia or hypertriglyceridemia and 47 and 67 percent, respectively, met criteria for these diagnoses at least once during their follow-up.[33] In this cohort, hypercholesterolemia was associated with multiple PI-containing regimens and undetectable HIV viral load as measured by RNA PCR. Hypertriglyceridemia was predicted by elevated body mass index and use of the PI ritonavir (RTV). These clinical findings of lipodystrophy and dyslipidemia have been treated with some success with diet, exercise, or lipid-lowering medications, although the lipid-lowering medications may result in drug-drug interactions when they are combined with antiviral agents.

Nutritional goals for HIV-infected children should include preservation of normal growth and development, provision of adequate amounts of all nutrients, and prevention of malabsorption and deficiencies of nutrients that alter immunologic function, all while improving quality of life.[175]

Malignancy

Human immunodeficiency virus infection has been associated with an increased risk for malignancy, both AIDS defining and non–AIDS defining.[76] Initiation of HAART in the mid 1990s has resulted in a significant decrease in AIDS-defining neoplasms such as Kaposi sarcoma and certain lymphomas, particularly primary CNS lymphoma and high-grade B-cell non-Hodgkin lymphoma, but malignancy continues to be reported.[57,76,104,128] The majority of malignancies that affect HIV-infected children are non-Hodgkin lymphoma.[104,133,141] In a retrospective study of 4954 children with AIDS in the United States (1978 to 1996), approximately 2.5 percent had documented malignant diseases: non-Hodgkin lymphoma (n = 100), Kaposi sarcoma (n = 8), leiomyosarcoma (n = 4), and Hodgkin disease (n = 2); 10 others had unspecified cancers.[12] Associated in situ infection with HIV, EBV, or both, has been documented in pediatric malignancies, although the precise role in pathogenesis is not defined. In a case-control study, a high viral burden of EBV was associated with the development of malignancy, but only in children with $CD4^+$ T cell counts >200/μL.[206] Early chemotherapeutic intervention has enhanced the quality of life and longevity and often has been provided in conjunction with antiretroviral therapy.

Kaposi sarcoma clearly occurs much less commonly in HIV-infected children. The pathogenesis of Kaposi sarcoma, both HIV and non–HIV related, has been elucidated, and human herpesvirus–8 has been documented in lesions.[117,152] Pathogenesis has been linked to oncogenesis and cytokine-induced growth. The clinical manifestations of Kaposi sarcoma associated with AIDS affect multiple organs. The skin, gastrointestinal tract, lungs, and heart have been affected by Kaposi sarcoma.[7] Management of Kaposi sarcoma has improved with increasing use of HAART to restore immune function in HIV-infected individuals.[200]

Leiomyomas and leiomyosarcomas are the second most common malignancies observed in HIV-infected children. Although this cancer is usually seen in the gastrointestinal tract, it may also involve the lungs or spleen. The pulmonary lesions are usually visible as nodules on the chest CT, whereas the gastrointestinal tumors present as evidence of obstruction, abdominal pain, and bloody diarrhea.[104] Since the advent of HAART, HIV-related malignant disease in the United States is reported less frequently. In a study of 2,969 HIV-infected children observed in the Pediatric AIDS Clinical Trials Group 219/219C from 1993 to 2003, only 37 cases of malignant

disease were reported, representing a prevalence of 0.6 percent malignancies and an incidence of 1.56 per 1,000 person-years.[133] In this analysis, the standardized incidence cancer rate for infected children was 10.08 as compared with uninfected exposed controls. The incidence of cancer was highest in children with severe immunocompromise and in those who had received HAART for less than 2 years. In contrast, developing nations continue to report high incidences of malignant disease.[241]

Other Complications

Cardiac Abnormalities

Cardiac manifestations of HIV infection in children include left ventricular dysfunction, increased left ventricular mass, myocarditis, and pericardial effusion.[266] Clinically, HIV-infected children have been described with congestive heart failure and cardiomegaly, cardiac tamponade, nonbacterial thrombotic endocarditis, conduction disturbances, and sudden death, presumably secondary to primary ventricular arrhythmia associated with severe cardiomyopathy. In a postmortem analysis of 30 HIV-infected children followed longitudinally in the prospective P2C2 HIV Multicenter Study, 50 percent had cardiomegaly with associated clinical findings of increased heart rate, increased left ventricular mass, and chronic heart disease.[131]

Asymptomatic children with HIV infection additionally have been documented to exhibit cardiac abnormalities. In a cross-sectional study of 49 HIV-infected children, carotid artery wall stiffness was larger and systolic-diastolic variations in diameter of the carotid artery were significantly lower compared with controls in the absence of cardiovascular risk factors.[16] Other investigators reported higher carotid intima-media thickness in HIV-infected subjects than in healthy controls, suggesting early atherosclerosis; duration of antiretroviral therapy and $CD4^+$ T-cell percentage were associated with these changes.[220]

A recent prospective cohort study of HIV-exposed infants suggested associations of in utero antiretroviral therapy exposure with reduced left ventricular mass and dimension and septal wall thickness z-scores and increased left ventricular fractional shortening and contractility up to 2 years of life.[154]

No evidence suggests that HIV is directly cardiotoxic, although HIV has been documented within myocardial cells by in situ hybridization.[82] Other factors may have an impact on the development of cardiac abnormalities and include malnutrition and infectious agents such as CMV and EBV.

The increasing use of HAART and, specifically, PIs in the pediatric HIV-infected population prompted careful management of associated hypercholesterolemia and hyperlipidemia. In univariate analysis, hypercholesterolemia in children with HIV infection treated with a PI regimen was associated with elevated systolic blood pressure but not with body mass.[79] Careful follow-up of lipid profiles should be evaluated routinely in HIV-infected children receiving antiretroviral therapy.

Renal Dysfunction

Renal disease is a well-known complication of HIV infection. HIV-1–associated nephropathy (HIVAN) is a clinical and renal histologic disease characterized by the presence of heavy proteinuria and nephrotic syndrome leading to a rapid progression to chronic renal failure. In a retrospective evaluation of 155 pediatric patients with AIDS, 12 were noted to have significant proteinuria.[250] The renal abnormalities described in HIVAN included nephritis (focal and segmental glomerulosclerosis and mesangial hyperplasia) and nephrosis.[169,251] The immunopathologic characteristics of HIVAN include inflammatory infiltrations predominantly composed of activated T cells ($CD4^+$ T cells usually exceeding $CD8^+$ T cells).[216]

Persistent metabolic acidosis associated with renal tubular disease and high anion gap acidosis has been reported in pediatric HIV infection.[216] Renal disease in HIV-infected children often appears in concert with profound immunodeficiency and end-stage HIV disease. Because most pediatric patients with AIDS and renal disease have perinatally acquired HIV infection, the importance of congenital or early concomitant infections (e.g., CMV) has been postulated to affect pathogenesis. Recent studies show that host genetic factors also play an essential role in HIVAN.[211]

The nephrosis of HIV disease can be particularly difficult to treat in an already malnourished, hypoproteinemic, HIV-infected child. HAART is considered the best treatment for HIVAN. Corticosteroids in combination with HAART may be attempted. However, the risks associated with their long-term use in HIV-infected children should be balanced against their potential benefits.[212] Many of the reported children with renal disease have associated growth failure. Nutritional supplementation and dietary restriction may be supportive adjunctive therapy.

Bone Marrow Suppression

Hematologic abnormalities associated with HIV infection in children include leukopenia, anemia, and thrombocytopenia. The etiology of neutropenia is often multifactorial in HIV-infected patients, representing the combined effects of systemic infection, medications, and HIV itself.[8] Neutropenia often has been described in association with circulating antineutrophil antibodies and may respond to blockade therapy with IVIG. Granulocyte colony-stimulating factor has been used successfully in neutropenia, both drug induced and HIV associated.[106,107,186]

The anemia of HIV infection may be microcytic, hypochromic as seen in chronic infection, autoimmune with positive Coombs testing, or typical of nutritional deprivation (iron or vitamin B_{12} deficiency). The origin of anemia in AIDS is difficult to sort out and is confounded by multiple cofactors that affect red blood cell counts, that is, poor nutritional status and concomitant use of toxic therapeutic agents (zidovudine). In adults and children, recombinant erythropoietin has been beneficial in treating anemia associated with antiviral therapy.[21] In

developing nations, infant anemia of HIV exposure or infection coupled with acute local parasitic infections (malaria) may significantly affect infant morbidity. The risk for developing severe and potentially fatal malarial anemia is increased for HIV-exposed or infected children with concomitant acute parasitemia, as compared with HIV-negative controls.[196]

Immune thrombocytopenia has been reported in 13 percent of children with symptomatic HIV infection with an onset as early as the first year of life.[97,165] Thrombocytopenia in HIV-1–infected patients is multifactorial, including a direct effect of HIV-1 with a depressed platelet production due to HIV infection of megakaryocytes, and peripheral destruction due to platelet-associated autoantibodies triggered by molecular mimicry between some HIV-1 peptides and membrane-associated platelet glycoproteins.[155] Therapy for thrombocytopenia in children and adults has included no intervention, platelet transfusions, systemic corticosteroids, IVIG, antiretroviral therapy, and, most recently in adults, IFN-α. Immune thrombocytopenia has resolved spontaneously in some children with simple supportive measures.

DIAGNOSIS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN INFANTS AND CHILDREN

Early Transmission to Fetuses

The human placenta plays a role in prenatal transmission of HIV infection from mother to fetus. Studies suggested that fetal infection can take place as early as 9 to 11 weeks of gestational age.[25,167] Preliminary examination of birth placental tissue from HIV-infected mothers in another study indicated that HIV core antigens could be detected in approximately 50 percent (23 of 51) of the cases studied; furthermore, HIV antigens were localized in the Hofbauer cells.[262] Finally, investigators documented that placental trophoblasts can be infected by CD4-independent isolates of HIV-1 in vitro.[4] Placental cytokines and chemokines influence HIV replication in trophoblasts. Genetic analysis of HIV-1 sequences verify the interaction of HIV-1 and placental tissue. The vertical transmission of HIV-1 is characterized by selection of genotype variants that escape the mother's immune system.[5]

An increase in the incidence of intrauterine fetal demise was demonstrated in the literature in HIV-infected pregnant women.[74] In HIV-negative fetuses, placental lesions known to be associated with fetal demise were identified: abruption, infarction, and other infections (e.g., CMV infection). In HIV-positive fetuses, similar placental lesions could not be identified and death was attributed to HIV infection of fetal tissue as detected by in situ hybridization. Two hypotheses for transmission are proposed: (1) direct cell-to-cell spread of HIV from infected maternal mononuclear cells through the placental cells and eventually to fetal tissue itself and (2) infected maternal cells that gain access to the fetal circulation.

TABLE 191B-6 **Guidelines for the Diagnosis of HIV Infection in Infants Born to HIV-Infected Mothers**

Diagnosis in Infants Aged <18 mo

Virologic assays that directly detect HIV, preferably HIV RNA assays or the HIV DNA polymerase chain reaction, must be used to diagnose HIV infection in infants aged <18 mo. A positive virologic test should be confirmed by a repeat virologic test on a second specimen.

Diagnosis in Infants Aged ≥18 mo

A positive HIV antibody test with confirmatory Western blot or immunofluorescent antibody (IFA) assay or virologic assay is used for diagnosis of infants aged ≥18 mo.

Exclusion of HIV Infection in infants

Definitive exclusion of HIV infection in non–breast-fed infants is based on two or more negative virologic tests, with one obtained at age ≥1 mo and one at age ≥4 mo, or on two negative HIV antibody tests from separate specimens obtained at age ≥6 mo.

Modified from Panel on Antiretroviral Therapy and Medical Management of HIV-Infected Children. Guidelines for the use of antiretroviral agents in pediatric HIV infection. Available at http://aidsinfo.nih.gov/contentfiles/lvguidelines/pediatricguidelines.pdf. Accessed November 25, 2012.

Methods Used to Diagnose Infection in Children Older Than 18 Months

In children older than 18 months in whom the presence of maternal anti-HIV antibody no longer is a confounding variable, the conventional tests used to diagnose HIV infection in adults are applicable (Table 191B-6). Thus, antibody detection tests including the HIV rapid test, enzyme immunoassays (EIAs), Western blot analysis, indirect fluorescent antibody assay, and p24 HIV antigen analysis (p24Ag), HIV culture, and HIV PCR assay may be used. The period between infection and detection of HIV antibody by a particular test is referred to as the "window period" for that assay. The window period for detection of HIV has been progressively shortened as EIA techniques have improved. Various generations of screening EIAs begin to detect anti-HIV antibody 2 to 6 weeks after HIV RNA is detected. EIAs that test for both HIV-1 and HIV-2 are used for screening. Western blots, which have been used for confirmation of positive screening EIAs, become diagnostically reactive 5 to 6 weeks after infection. Aside from the HIV-1 Western blot, confirmation of HIV-1 infection can be achieved with HIV RNA PCR (qualitative or quantitative) or HIV DNA PCR analysis. In addition, combined fourth-generation tests that detect both HIV p24 antigen and HIV antibody have been utilized for initial screening with confirmation of infection provided by HIV RNA PCR testing to reduce the window period for diagnosis in newer diagnostic algorithms.[18]

Methods Used to Make an Early Diagnosis of Infection in Infants and Children Younger Than 18 Months

The clinical manifestations of HIV infection in children are varied and nonspecific and include chronic pneumonitis, failure to thrive, hepatosplenomegaly, thrombocytopenia, and chronic diarrhea. In children younger than 18 months, a positive serologic determination of HIV is not accepted as indicative of the presence of HIV infection because of passive maternal antibody. Documentation of HIV infection in children younger than 18 months requires identification of viral components from blood. The most commonly used virologic assay in the United States is HIV PCR (DNA or RNA).[199] In resource-poor countries where virologic laboratories are not available, the CD4/CD8 ratio may be used to diagnose infants with HIV infection.[187]

Table 191B-6 outlines the current guidelines for determining positive HIV infection status in infants younger than 18 months who are born to HIV-infected mothers. Cord blood determinations for HIV are problematic because of contamination by maternal cells. Experience with the use of PCR in neonates born to HIV-infected women has documented HIV infection as early as the first days or month of life.[179] The estimated sensitivity of HIV DNA PCR assay, which can be used to measure integrated proviral HIV DNA, is 38 percent from birth to 48 hours of life, 93 percent by 14 days of age, and 96 percent by 28 days of age. HIV-1 RNA PCR measures extracellular viral RNA and has a sensitivity of 25 to 40 percent in the first weeks of life and 90 to 100 percent by the time the child reaches 2 to 3 months of age. The newer qualitative HIV RNA PCR assay has sensitivities similar to that of the HIV DNA PCR assay.

Current pediatric PCP prophylaxis guidelines suggest that infants with two negative virologic assays, both performed at 1 month or older and at 4 months or older, are not infected with HIV, and interruption of the therapeutic intervention is warranted.[37] Hence, early diagnosis in HIV-exposed infants has been improved both for identification of HIV-infected children (as early as the first month of life) and for uninfected children labeled as seroreverters (as early as the fourth month of life). Schedules for testing of HIV-exposed infants vary nationally. However, advances in diagnostic technology allow for early testing of HIV-exposed infants, including shortly after birth through 14 days of life, at 1 to 2 months of age, and then again at 3 to 6 months. Confirmation of negative virologic assays (HIV PCR) can be performed with typical antibody testing when the child is 18 months of age.

The assays outlined earlier easily detect HIV-1 subtype B HIV commonly found in developed nations. To detect non-B HIV infection in individuals from or in developing nations, HIV RNA PCR may be preferred, because it has a lower incidence of false-negative assays as compared with HIV DNA PCR. If non–subtype B HIV is suspected, then use of HIV RNA testing that is sensitive for these subtypes (e.g., more sensitive RNA PCR assays or branched DNA assays that are commercially available in the United States) should be considered.

IMMUNOLOGIC AND CLINICAL MONITORING OF HUMAN IMMUNODEFICIENCY VIRUS–INFECTED CHILDREN

Laboratory monitoring of HIV-infected children is linked to those variables that predict morbidity and mortality, namely, $CD4^+$ T-cell percentage and HIV RNA PCR assay results. Clinical evaluations should occur at a minimum of every 3 to 6 months, or sooner if the patient has clinical signs or AIDS-defining events, and measures of $CD4^+$ T-cell and HIV RNA PCR values should be performed. Because of variability across commercially available RNA PCR assays that may be as great as twofold, the individual HIV-infected patient should, when possible, be tested with a single assay type. Recommendations for changes in treatment based on changes in $CD4^+$ T-cell percentages or HIV RNA PCR should be undertaken in consultation with a specialist who routinely provides care to HIV-infected individuals. Evaluation of the individual HIV-infected child for viral resistance can be accomplished with use of commercially available phenotyping or genotyping assays. Such studies should be performed in consultation with an HIV specialist. Depending on treatment regimens, most children also should have laboratory studies performed to assess their potential for developing treatment-induced toxicities including bone marrow suppression, metabolic acidosis, dyslipidemia disorders, and pancreatitis. It is recommended that this cohort annually receive dental and ophthalmologic assessments as well as tuberculosis screening. Routine recommendations for childhood vaccine delivery are outlined later.

TREATMENT

Primary Anti–Human Immunodeficiency Virus Infection Treatment

Implementation of combination antiretroviral therapy consisting of at least three antiviral drugs has enhanced survival rates, improved immune status, and reduced opportunistic infections, as previously outlined.[24,98,168,215] Increased survival of HIV-infected children brings challenges in selecting successive new antiretroviral therapy regimens and specific issues to address include short- and long-term toxicities related to therapy and development of drug resistance.

In general, the principles of therapy are similar in all affected age groups. Treatment should be aggressive and use multiple drugs as early in the course of the infection as possible to suppress viral replication fully, reduce development of resistant viral strains, minimize drug-related toxicity, and preserve immune function. Considerations specific to the pediatric host include the following: (1) early clinical severity of HIV disease, viral load, and level of immune suppression; (2) availability of appropriate drug formulations and dosing; (3) unique pharmacokinetics (body composition, renal excretion, liver metabolism, enzyme maturation); (4) regimen

potency, complexity, short- and long-term toxicity potential; (5) impact of changing therapy; (6) comorbidities that affect drug choice; (7) drug interactions; and (8) the ability of the parent or child to adhere to a prescribed regimen.

Guidelines for initiation of therapy differ somewhat for adults and children. Current pediatric recommendations include initiation of therapy for all HIV-infected children, with the strongest support for the recommendation in symptomatic and immunosuppressed HIV-infected children and in children aged younger than 12 months regardless of clinical, immunologic, or virologic status (Table 191B-7). Current antiretroviral therapy is designed to target different steps in the replication cycle of HIV (Fig. 191B-6).[138] The Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children currently recommends aggressive combination of at least three medications from at least two drug classes for initial treatment of HIV-infected infants, children, and adolescents. With improvements in treatment formulations, dosing recommendations for antiviral agents can alter over time. Hence, for updated specific dosing and drug-drug interactions of antiviral agents, the reader is referred to guidelines from the Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children.*

Inhibitors of Human Immunodeficiency Virus Cell Entry

Entry of HIV-1 into target cells begins with interactions of the viral envelope protein gp120 with CD4 and a chemokine coreceptor, usually CCR5 or CXCR4. Both cellular receptors and structures in envelope proteins associated with membrane attachment and fusion are targets for therapeutic intervention.

Blockade of Human Immunodeficiency Virus by CD4-Receptor Inhibitors

CD4-based molecules can neutralize HIV by several mechanisms. Initial studies demonstrated the efficacy of soluble preparations of CD4 (sCD4) against HIV in vitro.[122,228,266] A chimeric molecule consisting of recombinant CD4 and immunoglobulin G (rCD4-IgG) was developed with an extended half-life and enhanced efficacy. Shearer and colleagues[237] documented safety, evidence of placental transfer, and appropriate elimination after intravenous administration of rCD4-IgG2 in pregnant women. In a phase I/II study, 18 children infected with HIV-1 received single or multiple intravenous doses of rCD4-IgG2 and demonstrated evidence of antiviral activity and tolerance.[236] Certain small molecules may competitively inhibit viral entry by binding gp120, thus blocking the gp120-CD4 interaction. It is generally considered that these small molecules in development as antiretroviral medications interfere with the gp120-CD4 interaction through altering the conformation of gp120

*Working Group on Antiretroviral Therapy and Medical Management of HIV-Infected Children guidelines: Available at http://AIDSinfo.nih.gov.

TABLE 191B-7 Treatment Recommendations for Initiation of Therapy in Antiretroviral-Naïve HIV-Infected Infants and Children

- Antiretroviral therapy should be initiated in all children with AIDS or significant symptoms (Clinical Category C or most Clinical Category B conditions) (AI*).
- Antiretroviral therapy should be initiated in HIV-infected infants <12 months of age regardless of clinical status, CD4 percentage or viral load (AI for infants <12 wk of age and AII for infants ≥12 wk to 12 mo).
- Antiretroviral therapy should be initiated in HIV-infected children ≥1 yr who are asymptomatic or have mild symptoms with the following CD4 values:
  - Age 1 to <3 yr
    - With CD4 T lymphocyte (CD4 cell) count <1000 cells/mm^3 or CD4 percentage <25% (AII)
  - Age 3 to <5 yr
    - With CD4 cell count <750 cells/mm^3 or CD4 percentage <25% (AII)
  - Age ≥5 yr
    - With CD4 cell count <350 cells/mm^3 (AI*)
    - With CD4 cell count 350-500 cells/mm^3 (BII*)
- Antiretroviral therapy should be considered for HIV-infected children ≥1 yr who are asymptomatic or have mild symptoms with the following CD4 values:
  - Age 1 to <3 yr
    - With CD4 cell count ≥1000 cells/mm^3 or CD4 percentage ≥25% (BIII)
  - Age 3 to <5 yr
    - With CD4 cell count ≥750 cells/mm^3 or CD4 percentage ≥25% (BIII)
  - Age ≥5 yr
    - With CD4 cell count >500 cells/mm^3 (BIII)
- In children with lower-strength (B level) recommendations for treatment, plasma HIV RNA levels >100,000 copies/mL provide stronger evidence for initiation of treatment (BII).
- Issues associated with adherence should be assessed and discussed with an HIV-infected child's caregivers before initiation of therapy (AIII). Patients/caregivers may choose to postpone therapy and, on a case-by-case basis, providers may elect to defer therapy based on clinical and/or psychosocial factors.

Rating of Recommendations: A = Strong; B = Moderate; C = Optional.

Rating of Evidence: I = One or more randomized trials in children† with clinical outcomes and/or validated end points; I* = One or more randomized trials in adults with clinical outcomes and/or validated laboratory end points with accompanying data in children† from one or more well-designed, nonrandomized trials or observational cohort studies with long-term clinical outcomes; II = One or more well-designed, nonrandomized trials or observational cohort studies in children† with long-term outcomes; II* = One or more well-designed, nonrandomized trials or observational studies in adults with long-term clinical outcomes with accompanying data in children† from one or more similar nonrandomized trials or cohort studies with clinical outcome data; III = expert opinion.

†Studies that include children or children and adolescents but not studies limited to postpubertal adolescents.

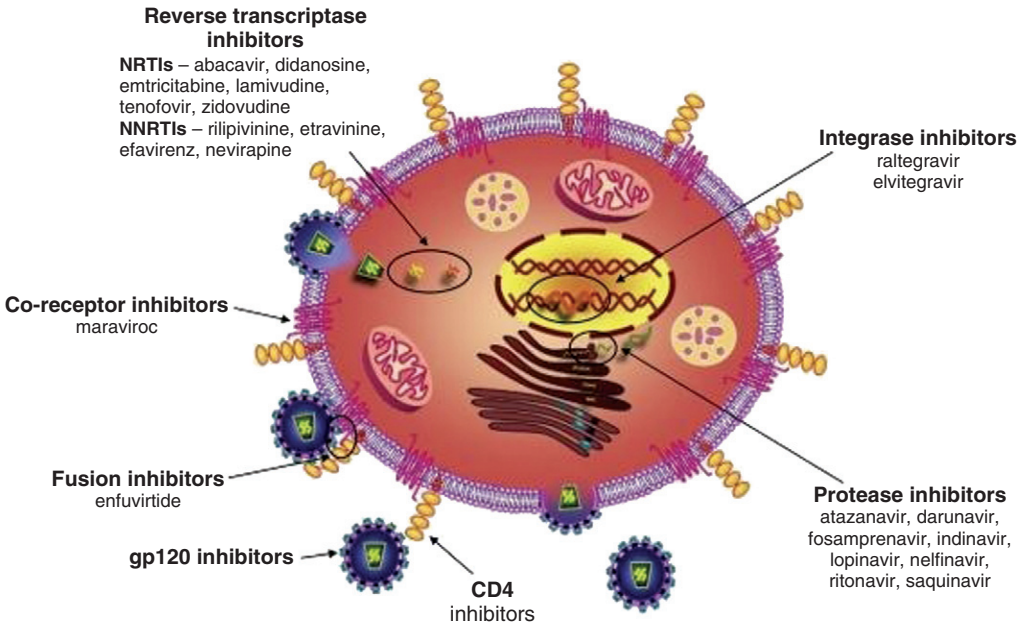

FIGURE 191B-6 ■ Inhibition of HIV-1 replication can be accomplished at different steps in the viral life cycle. (See companion Expert Consult website for color version.) (Modified from Pirrone V, Thakkar N, Jacobson JM, et al. Combinatorial approaches to the prevention and treatment of HIV infection. *Antimicrob Agents Chemother* 2011;**55**:1833.)

induced by CD4 instead of directly blocking CD4 binding.[64]

Blockade of Human Immunodeficiency Virus by Chemokine (Coreceptor) Inhibitors

Agents that target blockade of CXCR4 and CCR5 are being evaluated in clinical trials. Concerns about the use of coreceptor inhibitors include potential for unintended immune modulation and for viral escape to occur from tropism selection with resultant disease progression.[185] Maraviroc, a first-in-its-class selective CCR5 coreceptor antagonist, received approval by the U.S. Food and Drug Administration (FDA) for use in adults in August 2007. It is recommended as adjunct therapy to combination antiviral regimens and targets treatment of CCR5-tropic HIV-1 (R5 virus). The most common adverse effects are cough, fever, upper respiratory tract infections, rash, musculoskeletal symptoms, abdominal pain, and dizziness.

Blockade of Human Immunodeficiency Virus by Interference with gp120-CD4 Interactions

Polyanionic compounds such as dextran sulfate and heparin inhibit binding of HIV to the cell membrane, targeting the V3 loop of gp120.[184] Because of their systemic toxicity, most of these compounds have been evaluated in clinical trials as topical microbicides to prevent sexual transmission of HIV in humans. Unfortunately, clinical trials involving polyanion-containing microbicide formulations demonstrated that these products were ineffective and may have, in some circumstances, increased the risk for HIV-1 infection.[204] An additional substance, the green tea flavonoid epigallocatechin gallate (EGCG), binds to the CD4 molecule at the gp120 binding site, thus inhibiting gp120-CD4 interaction in a dose-dependent manner.[273] These adjunctive mechanisms to restrict HIV infection remain under development.

Blockade of Human Immunodeficiency Virus by Fusion Inhibitors

As previously described, fusion of the HIV envelope (glycoprotein gp41) with the target cell membrane is an important step in host cell infection. During fusion, FP of gp41 inserts into the target cell membrane and gp41 heptad repeats (HR1 and HR2) alter their conformation to form a six-helix bundle. This process results in the formation of a fusion pore through which the HIV capsid passes into the target cell. Fusion inhibitors represent the first class of entry inhibitors for which there is a licensed drug. Enfuvirtide (T-20) is a synthetic peptide that binds to the HR1 domain of gp41, prevents six-helix formation, and thus inhibits fusion.[50,214] Enfuvirtide is approved for use in HIV-infected adults and children aged 6 years or older whose HIV infection has not been controlled by other anti-HIV drugs. Addition of enfuvirtide to an optimized background regimen of antiretroviral therapy agents has demonstrated modest decreases of HIV viral load for long periods.[275] Although enfuvirtide is FDA approved for use in children, it is not commonly used because of its high cost, need for twice-daily subcutaneous injections, and high rate of injection-site reactions. The most common adverse effects include mild to moderate erythema, induration, pain, lymph node swelling, itching, and tenderness at the injection site. Other side effects reported are diarrhea, nausea, fatigue, headache, dizziness, peripheral neuropathy, and hypersensitivity reactions.[67] In the absence of a fully suppressive antiretroviral therapy regimen, mutations associated with resistance to enfuvirtide are demonstrated to be rapid.

Nucleoside Reverse Transcriptase Inhibitors

Nucleoside reverse transcriptase inhibitors (NRTIs) have no direct effect on HIV reverse transcriptase. After phosphorylation by the host cell kinases, they inhibit viral reverse transcriptase by competing with the natural substrate at the same binding site on the enzyme. With their incorporation into the newly forming proviral DNA, further viral transcription is prematurely terminated. Six NRTIs are licensed and currently available in the United States: zidovudine (ZDV), didanosine (ddI), stavudine (d4T), lamivudine (3TC), abacavir (ABC), and emtricitabine (FTC).

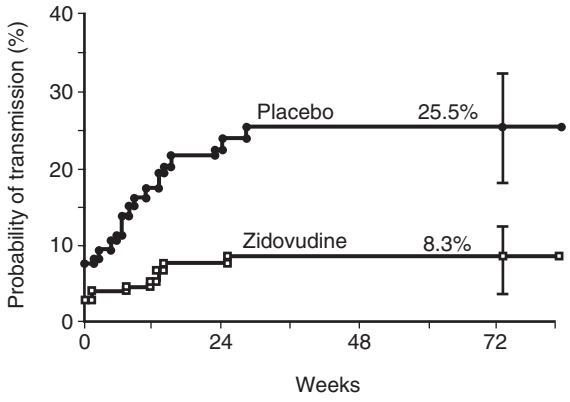
Zidovudine

Early pediatric studies demonstrated clinical, immunologic, and virologic improvements after intravenous and oral administrations of ZDV.[170] However, sustained $CD4^+$ cell restoration with ZDV monotherapy could not be achieved.[171]

ZDV is available in capsules, tablets, an oral solution, and an intravenous infusion. ZDV has good oral bioavailability (65%) and CNS penetration, with a mean serum half-life of 0.5 to 3 hours. It is rapidly metabolized in the liver by glucuronidation and is eliminated primarily by glomerular filtration and active tubular secretion. The most frequent adverse effects of ZDV are granulocytopenia and macrocytic anemia, often requiring limitations on doses. Some clinicians administer growth factors to counteract these adverse effects.[107] Other toxic effects include symptomatic myopathy, lactic acidosis, and hepatosteatosis.

In 1994, PACTG protocol 076 documented the remarkable effectiveness of ZDV in reducing the rate of maternal-infant transmission of HIV-1 by 66 percent (Fig. 191B-7).[61] The short-term toxicity most frequently described among infants was mild and reversible anemia. Most clinicians continue to use ZDV as part of their regimen to prevent maternal transmission, but maternal dosing includes additional antiviral medications to maximally suppress maternal viral load, and the administration of ZDV for maternal to child prevention of transmission is typically twice daily rather than the four times daily dosing used in the PACTG 076 trial.

ZDV and other NRTIs are suspected of inducing mitochondrial dysfunction secondary to their affinity for mitochondrial gamma DNA polymerase. This effect has been a source of particular concern for the ZDV- and HIV-exposed fetus and infant. Adding to this concern was a report from a large French study that 12 of 2644 NRTI- (predominantly ZDV) and HIV-exposed infants had evidence of mitochondrial dysfunction.[10] An additional 14 children in this cohort had unexplained symptoms that could be attributed to mitochondrial dysfunction. In response to this and other smaller cohort publications, the Perinatal Safety Review Working Group reviewed deaths in five large HIV-exposed perinatal cohorts (total of >11,000 NRTI- and HIV-exposed infants and children) in the United States to determine whether similar cases of severe mitochondrial toxicity could be documented.[73] Prophylaxis with ZDV was not associated with findings consistent with mitochondrial dysfunction, including a careful review of the cohort's 85 deaths. In early treatment studies, low birth weight and premature delivery were ascribed to NRTI exposure in small study cohorts.[158] With further treatment including HAART and specifically ZDV, low birth weight appears to be reduced in incidence.[231] Concerns about NRTI therapy in HIV-exposed but uninfected infants led to other large-scale studies that documented safety of the maternal-infant ZDV regimen through age 18 to 38 months.[112,245] Resistance to ZDV has been described, and the characteristic finding is a mutation at codon 215 of the reverse transcriptase.[124]



Placebo	183	84	42	37
Zidovudine	180	105	51	43

FIGURE 191B-7 ■ Analysis demonstrating a 66 percent reduction in perinatal transmission rates from 25 percent to 8 percent with antepartum, peripartum, and postpartum zidovudine therapy in HIV-infected pregnant women and their infants. (Reprinted by permission from Connor EM, Sperling RS, Gelber R, et al. Reduction of maternal-infant transmission of human immunodeficiency virus type 1 with zidovudine treatment. Pediatric AIDS Clinical Trials Group Protocol 076 Study Group. *N Engl J Med* 1994;**331**: 1173-80.)

Didanosine

In early studies, ddI was well tolerated and improvements in clinical and immunologic measures were documented in previously untreated HIV-infected children and those who had received prior ZDV treatment.[15,123,124] Didanosine is formulated as an enteric capsule with fewer gastrointestinal side effects and should be administered on an empty stomach. Common toxicities are diarrhea, abdominal pain, and nausea. The frequency of severe clinical toxicities, pancreatitis, and peripheral neuropathy is dose related. Lactic acidosis, severe hepatomegaly with steatosis, and retinal and visual changes also have been reported in patients treated with ddI. This drug may interact with other antiretroviral agents and produce toxicity or unwanted clinical outcomes. For example, ddI should be used cautiously in combination with tenofovir, a nucleotide inhibitor, because of increasing plasma levels of ddI and decreasing $CD4^+$ T-cell counts.[271]

Stavudine

Like ZDV and ddI, d4T is a potent inhibitor of in vitro HIV replication. In a phase I/II clinical trial of d4T in HIV-infected children, d4T was well tolerated without dose-related clinical or laboratory adverse events.[140] The oral bioavailability ranges from 61 to 78 percent, and the cerebrospinal fluid concentrations range from 16 to 97 percent 2 to 3 hours after oral administration.[139] Compared with ZDV, d4T is associated with better preservation of $CD4^+$ T cell counts.[137] d4T is available in capsules and as an oral solution. Reported severe toxicities include peripheral neuropathy, pancreatitis, lipodystrophy, and lactic acidosis. d4T and ddI should not be combined in the same regimen because of in vitro antagonism. d4T is no longer recommended for long-term use in pediatrics owing to concerns for toxicity, especially lipodystrophy.

Lamivudine

3TC has good antiviral potency to both HIV-1 and hepatitis B virus (HBV), and the drug is well tolerated orally and typically dosed twice daily.[203] 3TC is available in a tablet and a solution; its bioavailability is not affected by food. A combined product (Combivir) provides a preformed tablet formulation of ZDV (300 mg) and 3TC (150 mg). Toxicities are rare but include pancreatitis and lactic acidosis.[202]

Abacavir

ABC is approved for use in combination with other antiretroviral agents in children and adults. It is well absorbed, is unaffected by food, is well tolerated, and has good in vivo and in vitro potency in reducing HIV viral load when combined with other antiretroviral agents.[225] An important clinical side effect of this drug is ABC hypersensitivity reaction that occurs in approximately 5 percent of patients at a mean of 11 days after initiation of this agent.[67] Symptoms include fever, rash, malaise or fatigue, and gastrointestinal symptoms such as nausea and vomiting. HLA-B*5701 is documented to be a risk factor for development of hypersensitivity to ABC; U.S. guidelines recommend that ABC use is avoided in patients who are HLA-B*5701 positive.[246] Hypersensitivity to ABC requires permanent discontinuation of this agent because hypotension and death have occurred on repeat challenge. ABC is available in a tablet and an oral solution. A combined product, Trizivir, provides a co-formulated tablet of ZDV (300 mg), 3TC (150 mg), and ABC (300 mg). Epzicom is a co-formulated tablet containing 3TC (300 mg) and ABC (600 mg).

Emtricitabine

FTC was approved for use in combination with other anti-HIV medications. It is similar in many aspects to lamivudine and, like that drug, is active against both HIV-1 and HBV.[224] FTC has potent in vivo antiretroviral activity, has 4 to 10 times more potency than 3TC in vitro, is dosed once daily, and is well tolerated.[270] Because of cross resistance of FTC to the M184V resistance, mutations commonly observed in patients in whom a 3TC-containing regimen has failed, this agent has little utility in 3TC-experienced patients. It is available as a hard gelatin capsule and as an oral solution. Skin discoloration that manifests as hyperpigmentation on the palms and soles is a unique toxicity of FTC therapy and is usually mild.

Nucleotide Reverse Transcriptase Inhibitors

Nucleotide reverse transcriptase inhibitors (NtRTIs) function like previously described NRTIs, but they do not require phosphorylation. Tenofovir disoproxil fumarate (tenofovir DF, TDF), is an orally bioavailable prodrug of tenofovir. Tenofovir has good in vivo potency against both HIV-1 and HBV.[92] Tenofovir has long serum and intracellular half-lives that allow once-daily dosing. High-dose tenofovir treatment has been associated with skeletal abnormalities in young animals[265] and a significant decrease in absolute bone mineral density in HIV-infected children.[90] These changes in bone mineral density seemed to stabilize by 24 weeks of the treatment, and none of the patients experienced fractures during the study period. U.S. pediatric guidelines suggest judicious use in children and young adolescents because of unfavorable bone mineral density changes at a time when bone growth is so important. In addition, new onset or worsening of renal impairment has been reported in adults and children receiving tenofovir and may be more common in those with higher tenofovir trough plasma concentrations.[217] A combined product, Truvada, provides a preformed tablet formulation of FTC (200 mg) and TDF (300 mg) available for use once daily.

Non-nucleoside Reverse Transcriptase Inhibitors

Non-nucleoside reverse transcriptase inhibitors (NNRTIs) work by binding directly to the reverse-transcriptase enzyme, thus rendering it nonfunctional. Five available drugs in this class are approved for use in the United States: nevirapine (NVP), delavirdine, which is not recommended in pediatrics and will not be discussed further, efavirenz (EFV), etravirine (ETR), and rilpivirine (RPV). RPV, co-formulated with tenofovir and emtricitabine, has not currently been studied in pediatrics. The major disadvantage of the two drugs widely used in pediatrics in this category, NVP and EFV, is the rapid development of resistance with resultant cross resistance between the two drugs. A newer NNRTI, ETR, retains activity against NVP- or EFV-resistant viruses when used in a regimen that also contains darunavir/ritonavir and if the number of NNRTI resistance-associated mutations is limited.[23] Additional NNRTIs are in development.[267]

Nevirapine

NVP has been shown to have antiretroviral efficacy in a number of different combination regimens in children. A mainstay of therapy for infants and children in resource

limited settings, NVP also is used to reduce perinatal HIV transmission. Guidelines describing data supporting the use of NVP in perinatal HIV prevention are available through the Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission.[199]* NVP in three doses over the first several weeks of life has been shown to further reduce transmission of HIV when used in combination with the standard ZDV regimen for infants born to HIV-infected women who did not received antepartum antiretroviral drugs.[191] NVP is available in both tablet form, including a long-acting once-a-day formulation that is currently FDA approved for children 6 years old and older, and as an oral solution. Severe hepatotoxicity, hepatic necrosis, and hepatic failure have been reported in children typically occurring in the first 12 weeks of therapy. NVP should be discontinued permanently in children or adults who develop severe rash or rash with constitutional symptoms and hepatotoxicity. Women with $CD4^+$ T-cell counts greater than 250 cells/mm^3 have particularly increased susceptibility to nevirapine toxicity.

Efavirenz

EFV is approved as a single-daily dosing agent and for that reason has been attractive for use in adolescents and older children. It is available in capsule and tablet forms only. A fixed-dose tablet formulation, Atripla, provides a combination of FTC (200 mg), TDF (300 mg), and EFV (600 mg) available for use once daily in adolescents and adults. In addition to toxicities of rash and elevated aminotransferase levels, CNS abnormalities including somnolence, insomnia, bad dreams, irritability, and depression have been reported within the first 2 weeks of treatment. EFV has been reclassified as FDA pregnancy category D because in animal models EFV was associated with cleft palate and anencephaly.[31] Use in women of child-bearing age should include intermittent pregnancy testing and counseling for pregnancy prevention.

Etravirine

ETR is FDA approved for antiretroviral-experienced children and adolescents aged 6 to 18 years and is under study for use in younger children. It is available in tablet form and can be dispersed in liquids for those patients who cannot swallow tablets. ETR is associated with multiple drug interactions, which limits its use. ETR should not be coadministered with the following antiretroviral drugs: tipranavir/ritonavir, fosamprenavir/ritonavir, atazanavir/ritonavir, and unboosted protease inhibitors. It should not be administered with other NNRTIs (nevirapine, efavirenz, or rilpivirine). Limited data in adults suggest that ETR may reduce the trough concentration of raltegravir, but no dose adjustment is currently recommended when ETR and raltegravir are used together. ETR is often combined with ritonavir-boosted darunavir for treatment of HIV-infected adults with prior virologic failure, and this combination has been effective and well tolerated in small studies of HIV-infected adolescents.[142,258] More study is needed in pediatrics to determine optimal dosing.

Protease Inhibitors

PIs are relatively small peptides that share structural features with the substrates for viral protease. These molecules bind to and inhibit viral protease, thereby preventing the virus from maturing into an infectious virion. These drugs are extremely potent in reducing plasma RNA viral loads. They exhibit a high barrier for development of drug resistance. As a class, they interact with the hepatic cytochrome P-450 enzyme system, and many induce their own metabolism. Thus, the potential for significant drug-drug interactions is considerable. Examples of such interactions include those with oral contraceptives, antituberculous drugs, antiepileptic drugs, some antihistamines, and methadone. Adverse events of use of PI include previously described metabolic complications (dyslipidemia, lipodystrophy, insulin resistance, gastrointestinal effects of nausea or diarrhea), higher pill burden than with NRTI- or NNRTI-based regimens, and poor palatability of liquid preparations. Current PIs approved for treatment of HIV infection include saquinavir, RTV, lopinavir (LPV)/RTV, indinavir, nelfinavir (NFV), atazanavir (ATV), fosamprenavir (FPV), tipranavir (TPV), and darunavir (DRV). Previously used amprenavir is no longer manufactured in the United States. Saquinavir (high pill burden, must be boosted with another PI owing to low bioavailability, limited pediatric pharmacokinetics data) and indinavir (unfavorable toxicity profile and limited pediatric pharmacokinetics data) are not generally used in pediatrics and will not be further discussed.

Ritonavir

Ritonavir is a potent inhibitor of the hepatic cytochrome P-450 3A4 isoenzyme and therefore can improve the bioavailability and prolong the elimination half-life of most coadministered PIs.[62] This PI has been used as a pharmacokinetic booster in low doses combined with indinavir, LPV, saquinavir, FPV, ATV, TPV, DRV, and TPV to enhance these PI serum levels. It is available in capsule form and as an oral solution. When RTV is used at lower doses as a pharmacokinetic booster of other PIs in adults, it is used as 100 mg twice daily or 200 mg once daily. Side effects include nausea and vomiting, paresthesias, hyperlipidemia, and lipodystrophy.

Atazanavir

Atazanavir is FDA approved for use in children age 6 and older and adolescents, is available in capsule form, and is recommended in the U.S. pediatric treatment guidelines for both treatment-naïve and treatment-experienced children and youth whose HIV virus is sensitive to ATV.[198] RTV-boosted ATV is generally preferred over unboosted ATV and is used once daily in combination with NRTIs. The safety profile is notable for less gastrointestinal upset and fewer lipid perturbations than other

*Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission: http://aidsinfo.nih.gov/contentfiles/lvguidelines/PerinatalGL.pdf.

PIs, although lipid levels are higher when boosted with RTV. The most common toxicity of ATV is asymptomatic accumulation of indirect bilirubin due to inhibition of uridine glucuronosyl transferase 1A1; thus, ATV is not recommended for use in neonates. Efficacy when used in combination with NRTIs has been established in adolescents and in children.[22,135]

Darunavir

Darunavir boosted with RTV is FDA approved for use twice daily in combination with RTV in children aged 3 years and older as part of combination antiretroviral therapy. Several studies of treatment-experienced children given twice-daily DRV/RTV-based therapy has been shown to be well tolerated and efficacious.[14,126] Studies in treatment-naïve pediatric patients are ongoing. Diarrhea, vomiting, and rash are the most common side effects. The taste of the DRV liquid is better than the poor taste of the RTV needed for pharmacokinetic boosting; RTV liquid limits the palatability of this combination regimen.

Fosamprenavir

Fosamprenavir, the prodrug of amprenavir which is no longer manufactured, is approved and available in a pediatric liquid formulation and a tablet formulation, which must be given with food. FPV suspension is FDA approved for use in PI-naïve children as young as 4 weeks who were born at 38 weeks' gestation or later and have attained a postnatal age of 28 days and for use in pediatric patients aged 2 years or older.[84] The approval was based on two open-label studies in pediatric patients aged 2 to 18 years.[83] Overall, FPV is well tolerated and effective in suppressing viral load and increasing CD4 cell count; however, there is less pediatric experience with FPV than with LPV/RTV. The U.S. pediatric guideline recommends use only for children aged 6 months or older with RTV boost because unboosted FPV may result in low exposures and may select for mutations associated with resistance to darunavir.[198] FPV contains a sulfa moiety; rash is a side effect. Potential for cross sensitivity between FPV and other drugs in sulfonamide class is unknown.

Lopinavir/Ritonavir

Lopinavir/ritonavir (LPV/r) is a co-formulation of LPV and RTV. RTV acts as a pharmacologic enhancer rather than as an antiretroviral agent by inhibiting the metabolism of LPV and increasing LPV plasma concentration. It is available in tablet form (100 mg LPV/25 mg RTV; 200 mg LPV/50 mg RTV) and as an oral solution (80 mg LPV/20 mg RTV per milliliter; contains 42.4% alcohol by volume). LPV/r is widely used in pediatrics owing to efficacy, high genetic barrier to development of resistance, extensive experience in use in pediatrics, and availability in a liquid formulation. Currently, it is not recommended for use in neonates younger than 14 days of age or in premature infants younger than 42 weeks gestational age. Toxicities described in preterm infants include cardiac arrhythmias and dysfunction, lactic acidosis, acute renal failure, central nervous system depression, respiratory depression, and transient adrenal insufficiency.[119,239] Major toxicities are diarrhea, nausea, vomiting, headache, asthenia, and lipid abnormalities. The 42.4 percent alcohol content in this oral formulation leads to almost uniform symptoms of nausea or vomiting and often can be overcome with concomitant delivery of foods with strong tastes. Dosing compliance may be affected by taste and a caregiver's discomfort in delivery of this formulation.

Nelfinavir

Nelfinavir has been extensively studied in pediatric populations but, owing to lower potency, it is no longer widely used. NFV is not recommended for treatment in children aged younger than 2 years. It is available in tablet form. The most common side effects of NFV are diarrhea and lipodystrophy.

Tipranavir

Tipranavir is FDA approved for use as part of an RTV-boosted combination antiretroviral regimen in treatment-experienced children and adolescents age 2 to 18 years infected with HIV strains resistant to more than one PI. TPV is available as a capsule and as an oral solution. The boosting dose of RTV is higher than that for most PIs and is associated with more toxicity when used in combination, including nausea, diarrhea, vomiting, and hyperlipidemia. Also, TPV is associated with additional serious toxicity that limits its use, including hepatotoxicity, clinical hepatitis, and hepatic decompensation, including some fatalities; spontaneous bleeding in hemophiliacs; and increased risk for intracranial hemorrhage. TPV should be used with caution in patients who may be at risk for increased bleeding from trauma, surgery, or other medical conditions. TPV is associated with rash and contains a sulfa moiety.

Integrase Inhibitors

Joining of the viral genome and the host's chromosomal DNA is the hallmark of a retroviral infection. Integrase, the enzyme that catalyzes this step of the HIV life cycle, is an effective therapeutic target. On binding to specific sequences in viral DNA, HIV-1 integrase catalyzes two consecutive steps during integration: 3′ processing, endonucleolytic cleavage of the 3′ ends of the viral cDNA, and strand transfer, ligation of the viral 3′-OH cDNA ends to the 5′-DNA phosphate of an acceptor DNA (host chromosome).[208] Several compounds have been developed to block integration at different steps. Compounds that inhibit integrase at its catalytic site with an effect on strand transfer, known as strand-transfer inhibitors—raltegravir (RAL) and elvitegravir—are approved for use, and second-generation drugs are under development. Elvitegravir is available in a combination "quad" pill containing elvitegravir, a novel boosting agent with no antiviral activity named cobicistat, tenofovir DF, and emtricitabine. Elvitegravir has not been studied in pediatrics. Allosteric integrase inhibitors intended to interfere

with the integrase-LEDGF/p75 interaction are being designed; these new inhibitors, called LEDGINs, have an effect on 3′ processing and strand transfer.[163]

Raltegravir

Raltegravir is a first-in-its-class oral integrase inhibitor. RAL is available as a film-coated tablet or chewable tablet that are not interchangeable and is approved for use in 2- to 18-year-old patients. It is currently used as a preferred treatment in adults and for treatment-experienced pediatric patients. IMPAACT P1066 is a phase I/II open label multicenter trial to evaluate the pharmacokinetic profile, safety, tolerability, and efficacy of RAL in HIV-infected children. This study enrolled 126 treatment-experienced children and adolescents 2 to 18 years of age. Subjects received either the 400-mg film-coated tablet formulation (ages 6 to 18 years) or the chewable tablet formulation (ages 2 to <12 years). Of the 96 subjects studied at optimal dosing at week 24, 54 percent achieved HIV RNA less than 50 copies/mL; 72 percent achieved HIV RNA less than 400 copies/mL or 1 $\log_{10}$ or more HIV RNA drop from baseline. The mean CD4 count (percent) increase from baseline to week 24 was 119 cells/mm^3 (3.8%).[84] Side effects include rash, including Stevens-Johnson syndrome, hypersensitivity reaction, and toxic epidermal necrolysis; nausea; diarrhea; headache; fever; creatine phosphokinase elevation; muscle weakness; and rhabdomyolysis.

Supportive Treatment

Preventive measures applicable to immunodeficient individuals should be considered for the HIV-infected child. Examples include measles, influenza, and varicella prophylaxis after exposure. Additionally, routine childhood health care preventive measures, including adequate nutritional support, age and developmentally appropriate stimulation, dental and skin hygiene, and immunizations, should be offered to children with HIV infection or AIDS. The live viral measles-mumps-rubella vaccine is recommended for all HIV-infected children except those who are severely immunosuppressed ($CD4^+$ T-lymphocyte percentages <15 percent). The first dose is recommended as soon as possible after the first birthday, and the second dose should be given as soon as 1 month after the first dose to ensure early seroconversion. Varicella vaccine is recommended for HIV-infected children without significant immune compromise as well. Eligible children should receive two doses 3 months apart, with the first dose administered as soon as possible after the first birthday. Immunization for pneumococcus includes routine immunization with the conjugate pneumococcal vaccine. In addition, children aged 2 years or older also should receive the 23-valent pneumococcal polysaccharide vaccine 2 or more months after their last PCV dose. Influenza vaccine should be administered yearly starting at age 6 months. Patients with HIV infection are at increased risk for acquiring meningococcal disease. Meningococcal conjugate vaccine (MCV4) is preferred in patients aged 11 to 55 years and now is approved for use in 2- to 10-year-old children.[41]

The newer quadrivalent human papillomavirus (HPV) vaccine, Gardasil, is a vaccine consisting of noninfectious HPV-like particles. It is now recommended in a three-dose schedule for girls and boys aged 11 to 12 years, although it may be administered from as young as 9 years to 26 years.[41,48,213]

Immune-Based Therapies

The cardinal immune manifestation of HIV infection is the development of progressive $CD4^+$ lymphopenia with resultant clinical disease associated with severe immunodeficiency. Therefore, replacement of the $CD4^+$ T-lymphocyte pool is a logical approach for immune-based therapies.[235] Immune modulators have been assessed as single therapeutic agents or in combination regimens in adult clinical trials. An immune-based therapy, IL-2, demonstrated $CD4^+$ T-cell count increases but no clinical benefit in two large randomized studies.[1] Currently, other immune-based therapies (e.g., gene therapies, growth hormone, IL-7) are under investigation and should only be used in the treatment of HIV in the context of a clinical trial. IFN-α initially was studied as a therapeutic agent for Kaposi sarcoma with good response rates, but significant side effects limit its use in HIV infection. The utility of immune-based therapies in pediatric or adolescent HIV infection may include their use in treatment of concomitant chronic hepatitis B and C virus infection or HIV-associated immune thrombocytopenia.[54]

Chronic immune activation has been associated with poor outcomes—both AIDS-defining and non–AIDS-defining clinical events—in addition to persistent $CD4^+$ T-cell depletion. The cause of chronic immune activation in well-controlled HIV infection in the era of combined antiretroviral therapy, aside from coinfecting pathogens, may include low-level viral replication and microbial translocation. Therapeutic interventions that target immune activation including interfering directly with activation and inflammatory pathways are being developed.[30]

Vaccines

Goals for the development of an HIV vaccine include prevention of persistent HIV infection, prevention of severe clinical disease (AIDS), and therapeutic immunization to control HIV infection. The first candidate preventive vaccines tested in human trials in the late 1980s were based on the HIV-1 envelope glycoproteins gp120 or gp160, an approach aiming to induce neutralizing antibodies. The major limitations of this approach were lack of neutralizing antibody activity against a diversity of primary patient isolates of HIV-1 because of genetic variability and structural complexity of the HIV-1 envelope glycoproteins and absence of envelope-specific cytotoxic T-lymphocyte responses.[102,132,166] Currently, more than 30 HIV vaccines have been tested in human trials.[220,231] The vaccines had produced disappointing results until a recently completed HIV-1 vaccine efficacy trial in Thailand (RV144) showed that priming with a recombinant canarypox vector (vCP1521) and boosting with this

vector plus bivalent gp120 protein (AIDSVAX B/E) provided partial protection against HIV infection in heterosexual men and women.[219] Subsequent study has shown that the peak neutralizing antibody response (Nab) in RV144 was substantially weaker than the peak Nab response in a study of AIDSVAX B/E in injection drug users that showed no efficacy.[183] The results suggest either that weak neutralizing antibody responses can be partially protective against HIV in low-risk heterosexual populations or that the efficacy seen in RV144 was mediated by other immune responses, either alone or in combination with neutralizing antibodies.

Antigenically diverse viruses including HIV do contain highly conserved exposed sites, usually associated with function, which can be targeted by broadly neutralizing antibodies, and advances in the field have enabled increasing numbers to be identified.[29] Molecular characterizations of the antibodies and of the HIV antigens that they recognize offer new hope for the discovery of new vaccines and drugs.

PROGNOSIS

Mortality and morbidity rates for children and adolescents with HIV infection have declined dramatically. Effective efforts directed toward early diagnosis have allowed for earlier administration of primary viral therapy to prevent HIV transmission and prompt treatment and prevention of opportunistic infections. However, owing to untreated HIV disease, transmission of HIV is ongoing and opportunistic disease and death still affect HIV-infected pediatric populations worldwide. Public health strategies to slow these outcomes are continuing. Pediatric research should continue to address therapeutic interventions that allow for care of now chronically infected children and adolescents who are surviving and striving to contribute to their world. In addition, careful follow-up of HIV-exposed and neonatal antiviral-exposed individuals should be a priority in an effort to investigate long-term outcomes in individuals exposed to mother-to-child prevention regimens.

For developing nations, resources and research to stem the continued tide of HIV infection are of paramount importance. Efforts must be made to reduce global perinatal transmission rates further and to define HIV detection methods that allow earliest intervention in affected children. Effective vaccine development clearly would have a significant and worldwide impact on adults and children exposed to HIV.

Research and prevention initiatives must now be coupled with socioeconomic and political efforts to find the will to sustain a global impact on HIV transmission and treatment. Duplication of the achieved successes in preventing perinatal transmission in industrialized countries is needed desperately in sub-Saharan Africa, East Asia, and Central America, where competing medical needs limit available local funding for prevention of HIV transmission and for HIV treatment. When viewed from this perspective, placing the highest priority on global confrontation of this epidemic that threatens the future of our children is imperative.

Transmissible Spongiform Encephalopathies (Creutzfeldt-Jakob Disease, Gerstmann-Sträussler-Scheinker Disease, Kuru, Fatal Familial Insomnia, New Variant Creutzfeldt-Jakob Disease, Sporadic Fatal Insomnia)

William J. Britt • Gail J. Harrison

The group of neurodegenerative diseases classified as transmissible spongiform encephalopathies (TSE) represents a subset within a group of diseases that also have been termed *infectious amyloidoses* or *cerebral proteopathies*.[196,246] Although it has been speculated that all neurodegenerative diseases may be prion diseases, the TSE[93,179] are characterized by progressive cortical dysfunction linked to the accumulation of insoluble, proteinaceous aggregates in the central nervous system (CNS) (Table 192-1). The protein aggregates characteristic of

TABLE 192-1 Naturally Occurring Transmissible Spongiform Encephalopathies

Host	Disease
Human	Kuru
	Creutzfeldt-Jakob disease
	Sporadic
	Familial
	Infectious
	Variant Creutzfeldt-Jakob disease
	Gerstmann-Sträussler-Scheinker syndrome
	Fatal familial insomnia, sporadic fatal insomnia
Sheep, goats	Scrapie
Mink	Transmissible mink encephalopathy
Deer, elk	Chronic wasting disease
Cattle	Bovine spongiform encephalopathy, bovine amyloidotic spongiform encephalopathy
Cats	Feline spongiform encephalopathy

these diseases are composed of polymeric fibrils of a host-encoded protein deposited in several different regions of the CNS and within other organ systems, particularly in lymphoid organs. Amyloid may be present in TSE, and its role in the pathogenesis of these diseases is uncertain. However, the symptoms associated with the spongiform encephalopathies are thought to arise from cellular and end organ dysfunction associated with the abnormal deposition of an isoform of a normal cellular protein, PrP^c, encoded by the *PRNP* gene.[12,37,73,196] The physiologic function of PrP^c remains incompletely defined, and no null alleles of the *PRNP* gene have been identified, raising the possibility that some of the symptoms associated with these diseases are caused by a loss of normal PrP^c function.[175] Although the biologic determinants of the phenotypic expression and variation of Creutzfeldt-Jakob disease (CJD) are not clear, there is a suggestion that prions may exist as multiple prion strains or genotypes that may influence disease expression and the prion propagation may also be associated with production of toxic species, which cause disease.[74,99,138] Six subgroups, (MM1, MM2, MV1, MV2, W1, and VV), based on prion protein codon 129 genotype and biochemical characteristics of PrP have been proposed to correlate with transmissibility and with the clinical and pathologic features of CJD.[20,106,211] The TSE share several clinical features with other cerebral amyloidoses, and the insoluble protein aggregates exhibit biophysical properties similar to plaques found in Alzheimer disease, currently the most common cerebral proteopathy.[93] In contrast to these diseases, the TSE can by definition be transmitted by parenteral inoculation or by other less efficient routes, such as ingestion of contaminated tissue from the nervous system.

TSE were diseases recognized only in domestic livestock in northern Europe until late in the 20th century. Scrapie, a disease of sheep, was described first in the mid 1700s.[37,218] Farmers realized early on that the agent responsible for scrapie is communicable and instituted control measures that included isolation and destruction of affected animals and herds.[37] Evidence has suggested that the scrapie agent can persist in contaminated soil for at least 16 years, a finding that explains the reported recurrences of this disease in flocks that had been culled decades earlier.[101] Although farmers were aware of the communicability of scrapie between herds of sheep and had documented its spread among sheep, its transmissibility was not formally demonstrated until 1936.[82] Shortly thereafter, scrapie developed in a flock of sheep that were inoculated with a vaccine for louping ill prepared from CNS tissue derived from sheep that had been exposed to scrapie.[37,218] Together, these reports provided definitive evidence of the transmissible nature of scrapie. The term *slow virus disease* was initially coined by veterinarians to describe the natural history of this curious group of diseases in domestic animals that included a prolonged incubation period measured in years and a relentlessly progressive clinical deterioration once symptoms appeared.[220] This term was used to describe this group of diseases until the 1980s, when investigators began to consider that although the agent responsible for the spongiform changes in scrapie-infected mice is transmissible, it cannot be classified as a conventional virus. A decade earlier, the observational and laboratory studies of kuru, a progressive cerebellar ataxia and dementia that occurred predominantly in adolescent and young adults of the Fore tribe in Papua New Guinea, provided an important piece of the puzzle of the etiology of this group of diseases.[3,105] The natural history of kuru was described initially by Vincent Zigas and Carleton Gajdusek and was noted to be associated with the ritual cannibalism practiced by this tribe. In 1959, an astute veterinary neuropathologist, William Hadlow, observed a striking similarity of the spongiform changes in the brains of patients with kuru to the brains of sheep with scrapie and suggested that these two diseases could be caused by similar mechanisms, possibly a transmissible agent.[114] Considering the possibility that kuru is caused by a transmissible agent, Gajdusek and coworkers[95-97] eventually demonstrated that the clinical and histopathologic findings of kuru can be transmitted to chimpanzees and other nonhuman primates by inoculation of brain tissue from patients with kuru. Interestingly, Gajdusek and coworkers initially thought that the experiment was a failure because the animals did not become symptomatic until nearly 2 years (18 to 21 months) after intracranial inoculation was performed, and later reports from this same laboratory indicated that nearly 20 years elapsed between the inoculation and the development of disease in some chimpanzees.[14,37] Subsequent studies by other investigators have demonstrated that brain homogenates from patients with CJD, Gerstmann-Sträussler-Scheinker (GSS) disease, fatal familial insomnia (FFI), and, most recently, variant CJD (vCJD) can transmit spongiform changes to nonhuman primates.[22,26,194] A variant of FFI, sporadic fatal insomnia, has been identified and added to this group of transmissible neurodegenerative diseases.[172,188] The hypothesis that transmissible neurodegenerative diseases are caused by a protein was suggested first by Griffith[113] in 1967 and later more extensively developed by Prusiner[194] and coworkers. The claim that the etiologic agent of scrapie is an isoform of a normal

host protein, PrP^c (alternatively referred to as prion protein), that can transmit disease in the absence of nucleic acid was met initially with great skepticism and even today continues to evoke debate.[64,65,168,194] During the ensuing decade, the hypothesis that a protein can promote the formation of a polymeric fibrillary, insoluble plaque without the requirement of nucleic acid encoding a protein of an infectious agent has been supported by studies from several laboratories. This hypothesis represented a paradigm shift in biology, and Stanley Prusiner was awarded a Nobel Prize in 1997 for his groundbreaking studies of prion diseases. Interestingly, approximately 20 years earlier, Gajdusek also was awarded a Nobel Prize for his description of the transmissible nature of kuru and similar diseases of the CNS.

An important chapter in the TSE saga is the appearance of mad cow disease (bovine spongiform encephalopathy [BSE]) in Great Britain in the mid 1980s; and by the late 1990s, nearly 200,000 diseased animals had been destroyed.[49] Mad cow disease has been discovered in cattle in several countries within Europe and most recently in the United States. Of greatest concern has been the transmission of BSE to more than 100 individuals in Great Britain and the report of at least three cases in France.[49] BSE has been reported in the United States, and a significant increase in the incidence of TSE of elk and deer (chronic wasting disease) has been reported in wild game farms in the western United States as well as in wild deer herds in the midwestern United States.[173,247] Because of the concern that large numbers of human cases could eventually develop secondary to contamination of food products and pharmaceutical reagents with BSE or through contact with contaminated tissue from deer or elk, substantial interest has developed in the study of TSE.

EPIDEMIOLOGY

The natural history of human TSE usually is described in the context of the epidemiology of CJD. Three different modes of acquisition of disease have been described: (1) sporadic, (2) inherited mutations in the cellular gene encoding PrP^c (genetic), and (3) acquired or infectious following exogenous exposure to prion-contaminated material, such as after neurologic procedures (infectious) (see Table 192-1). Little is known about genetic or environmental factors that contribute to the development of sporadic forms of these diseases, although numerous epidemiologic studies have claimed associations ranging from ingestion of mutton to exposure to blood products after surgery.[4,41,80,171] Common migratory scavenger birds, such as crows, also may play a role in the geographic spread of TSE diseases.[241]

Studies in cases of CJD have revealed numerous genetic mutations in the cellular gene encoding the normal cellular prion protein, PrP^c, associated with the development of disease, and they have been defined as genetic causes of CJD and other TSE (see following discussion).[140] Polymorphism in the methionine at position 129 in the coding sequence of PrP^c is the genetic polymorphism most commonly recognized as being associated with sporadic CJD.[187] Homozygosity at methionine 129 of PrP^c is seen in 64 to 81 percent of patients with sporadic CJD yet is present in only approximately 39 percent of the general population and is thought to predispose an individual to both iatrogenic and sporadic CJD.[2,187,255] Interestingly, valine homozygosity at this position was associated more frequently with cases of CJD with onset in those younger than 40 years.[2] Furthermore, a retrospective analysis of a small number of patients with kuru revealed that all were homozygous for methionine at position 129 and all had more rapidly progressive disease with a shorter incubation period than did other patients with kuru from this cohort.[157] In Papua New Guinea, Fore women surviving exposure to contaminated material during the ritual cannibalistic feasts were shown to be more likely to be heterozygous at methionine 129 (76%) than were similarly aged Fore women who had not been exposed to the cannibalistic feasts.[175] This result suggested that heterozygosity at methionine 129 provided a survival advantage. Population geneticists have argued that haplotype diversity at codon 129 of the PRNP may have been in response to an epidemic of prion disease. If so, this response would represent a recent balancing selection in humans.[175a,175b] The codon at position 129 also appears to modulate the clinical course of inherited TSE such as FFI, and patients homozygous for methionine at position 129 have a more rapid clinical course than do patients heterozygous at this codon.[181] Polymorphisms in the PrP^c, including those that occur at position 129, have not been associated with the development of vCJD after exposure to BSE-contaminated material; in fact, all human cases in Great Britain have been homozygous for methionine at position 129.[135] Heterozygosity at methionine 129 is thought to confer resistance by inhibiting PrP^c protein:protein interactions.[187] Interestingly, sequence analysis of the *PRNP* gene from populations throughout the world suggested that the observed increased frequency of heterozygosity at position 129 could be explained by widespread cannibalism among primitive humans and selection of methionine 129 heterozygotes secondary to increased disease penetrance associated with exposure of susceptible methionine 129 homozygotes to prion-contaminated tissue.[175] This conclusion has been challenged by other investigators.[222]

Sporadic CJD is the most common TSE in humans and accounts for approximately 85 percent of all cases of CJD.[41,140] It occurs worldwide at a rate of approximately $1/10^6$ population.[41] CJD is a disease of late middle age, with a mean age at onset of 55 to 65 years. Cases of CJD range from 20 to 84 years, with the youngest cases being described in patients 16 to 18 years old.[40,90,180] Little evidence exists for case-to-case transmission of CJD, with the obvious exception of cases resulting from iatrogenic transmission of CJD.[62] Vertical transmission of CJD has not been reported in studies of human CJD. Anecdotal reports of occurrence of CJD in the spouses of individuals with CJD raise the possibility of horizontal transmission.[43] Alternatively, disease in spouses could result from shared environmental exposures. Sporadic cases of non-CJD TSE previously thought to be caused solely by genetic mutations have been reported, thus extending the

spectrum of TSE in humans.[158,172] With the exception of cases that can be linked to an inherited genetic mutation, no epidemics of CJD have been reported, an observation that led British epidemiologists to suspect that a link exists between what was initially thought to be an increased frequency of CJD in young adults and the outbreak of BSE in the British Isles.*

Genetic mutations in the cellular prion gene, *PRNP*, can result in a variety of inherited TSE and are likely to account for the reported outbreaks of TSE in isolated populations. Because of the relatively late onset of disease even in patients with well-characterized mutations in *PRNP*, the possibility that TSE are inherited diseases of the CNS was not considered until more recent studies of the host cell origin of prions and the discovery that a cellular gene encoded the pathogenic protein associated with TSE. Estimates from various studies suggest that between 5 and 15 percent of cases of CJD may arise from mutations in the cellular *PRNP* gene.[40] Genetic linkage studies have demonstrated that TSE are inherited as an autosomal dominant trait, an observation consistent with several studies in families with FFI and GSS.[21,131,176] In addition, defined mutations in *PRNP* have been shown to account for the increased rate of TSE in either geographically or ethnically isolated populations, such as Libyan-born Jews, an ethnic group with an incidence of TSE nearly 40 times greater than that observed in other populations.† A large number (>20) of mutations in *PRNP* have been described and appeared to be scattered throughout the gene. Reported mutations include both point mutations in the coding sequence changes, resulting in amino acid substitutions, and octapeptide insertions.‡ Because mutations in *PRNP* by definition are not present in cases of sporadic CJD, mutations of this cellular gene are not thought to play a direct role in the development of CJD in these individuals. Thus, the mode of acquisition of the TSE agent in these individuals has not been defined. In sporadic cases of CJD, the proposal has been made that spontaneous generation of the TSE agent could be occurring extremely infrequently and result in CJD. However, when scrapie was eliminated in sheep in New Zealand and Australia by culling diseased herds, spontaneous development of scrapie has not been described in these herds, suggesting that spontaneous development of the agent of TSE leading to scrapie in sheep is almost nonexistent.[65] In most cases, disease secondary to a genetic mutation in *PRNP* develops in patients of middle age, suggesting that although these diseases exhibit an autosomal dominance inheritance, the genetic background of the host contributes significantly to the observed phenotypes.

Although farmers and neuropathologists were well aware that scrapie is readily transmissible, the possibility that human TSE also are transmissible was not demonstrated until Gajdusek and coworkers defined the natural history of kuru in the Fore tribe in Papua New Guinea.[3] Kuru was seen most commonly in adolescent and young adults of both sexes but only in older women. The disease was common, with an incidence of 1 percent in this tribe, and was a significant cause of death in this population.[3] Gajdusek carried out a detailed observational study of the Fore people, including their ritualistic cannibalism of the dead. This ritual included homogenization of the brains of dead relatives in bamboo cylinders with use of crude hand tools. The brain was reportedly ingested as well as smeared over the body by relatives and other members of the tribe. During most of their childhood, the Fore children remained with their mothers and other women of the village, including the time spent preparing the brains of dead relatives for ritual cannibalism. It is during this time that the exposure to the agent responsible for kuru was thought to occur, either by ingestion of the contaminated brain material or through skin abrasions that were present secondary to the nearly universal scabies infestation. Gajdusek and coworkers hypothesized that kuru is caused by an infectious agent and injected homogenates prepared from the brain of a deceased kuru patient into nonhuman primates; following an incubation period of more than 2 years, a disease similar to kuru was observed in the experimental primates.[14] After the transmissibility of kuru was demonstrated in experimental animals, several other TSE were shown to be transmissible in nonhuman primates and other experimental animals.[14,45,76,230,232] Subsequent studies demonstrated that kuru could be transmitted to nonhuman primates by oral ingestion of contaminated tissue.[103] Although the origin of the TSE agent responsible for kuru in the Fore tribe is unknown, the most plausible explanation is that a spontaneous mutation in the cellular PrP^c gene resulted in a case of TSE in the Fore tribe that then was introduced and propagated in the population by cannibalism. After ritual cannibalism was halted by the government of these districts in Papua New Guinea, new cases of the disease disappeared, and the last case of kuru in an individual younger than 30 years was reported in 1985.[3] Cases of kuru have developed some 40 to 50 years after exposure to infectious material, illustrating the prolonged incubation period of these diseases.[77,78,148]

Before the 1980s, cases of TSE occurring in children and adolescents, with the exception of kuru, were either extremely rare or not recognized. In the late 1980s, cases of TSE resembling CJD were reported in young adults who as young children had received injections of human growth hormone prepared from cadaveric pituitary glands.[36,45,47] The thought was that the practice of pooling pituitary glands from a large number of cadavers increased the risk of contamination of the preparation with prions from subclinical cases of TSE. More than 100 cases of TSE occurring after patients were injected with contaminated growth hormone preparations have been reported.[61] Whether new cases of TSE will develop in adults given cadaveric growth hormone before the mid 1980s remains uncertain, but with a mean incubation period of 12 years in documented cases, it is unlikely that significant numbers of new cases will be reported.[38,47] Other sources of TSE include dura grafts, corneal transplants, contaminated stereotaxic neurosurgical equipment, and, more recently, blood transfusions.* An alarming case of TSE

occurred in a chimpanzee after the use of a stereotaxic electrode that 2 years previously had been used in a procedure involving a patient with CJD. Because this electrode had been decontaminated numerous times with conventional sterilization methods before its use in this experimental animal, this case illustrated the potential for the occurrence of iatrogenic transmission of TSE to humans undergoing neurosurgical procedures.[104] Two confirmed and two probable cases of vCJD occurring after receipt of blood transfusions have been described in Great Britain.[115] Studies of experimental models of TSE, primarily scrapie in mice, have shown that the scrapie agent initially amplifies in titer in spleen and regional lymph nodes and enters the CNS by a bloodborne route or by infection of the peripheral nervous system.* In addition, studies in mice have demonstrated that brain tissue from animals injected with hamster scrapie can harbor the infectious agent for a prolonged time without evidence of disease.[123,202] Even during a period of inactive persistence and replication, the scrapie prion could be detected, suggesting that transmission of prion disease by contaminated blood products or surgical instruments may occur even if screening assays for the detection of prions are mandated.[189] To further cloud the issue, other investigators have postulated that less virulent strains of prions can attenuate the virulence of other strains of prions, which then can be transmitted readily during asymptomatic periods.[170,243] After transmission to a secondary host has occurred, the phenotype of the more virulent strain could be expressed. These findings are particularly worrisome because of the possibility that food products from cattle with subclinical BSE could continue to be consumed. Similarly, the possibility exists that the low incidence of vCJD in Great Britain, in spite of what most authorities consider was a much larger exposure to BSE before eradication of BSE-containing herds, could be explained by persistence of infectious agents in genetically resistant individuals or possibly be secondary to persistence in non-CNS organ systems.[29,123] Previously, these studies raised the possibility that TSE could be acquired by transfusion of blood and blood products obtained from infected hosts.[156]

Considerable controversy existed about the importance of transmissibility of TSE by blood and blood products.[120] Investigators argued that the risk is exceedingly small on the basis of experimental studies in rodents and epidemiologic studies involving patients receiving quantities of blood products, such as hemophiliacs. However, at least four patients are believed to have contracted CJD from blood transfusions and at least one from human plasma–derived clotting factor.† However, BSE has been transmitted to sheep by blood transfusions, and buffy coat preparations have been shown to transmit TSE to experimental primates.[25,130] The U.S. Food and Drug Administration has recommended a very conservative policy for blood and blood products because of these theoretical concerns, and, more recently, this policy has been reinforced by the reports of blood transfusion–acquired vCJD.[119,159,259] In addition to the exclusion of donors with symptoms consistent with TSE, individuals who have lived in or visited Great Britain and other countries with BSE for a cumulative period of 3 months during the interval of 1980 to 1996 are also excluded as donors.* With the possible exception of kuru, little evidence was available previously to suggest that TSE such as CJD could be acquired by ingestion of contaminated tissue.[41] This claim was challenged in the early 1990s by the reports of several young adults with CJD in Great Britain.[81,253] Inspection of the rates of CJD in England revealed that the incidence of CJD was approximately 15-fold higher than earlier, based on surveillance studies from previous decades.[36] In the years preceding the startling increase in rate of CJD, the cattle industry in Great Britain was being devastated by the spreading epidemic of BSE, a disease ultimately shown to be a TSE.[117,221,251] A similar disease had been noted in domestic cats as well as in animals housed in zoos, where they had been fed British beef and beef byproducts.[26,77,221] The first case of human disease thought to be associated with BSE was termed *vCJD* and was described in 1995, about 10 years after the first cases of BSE were reported in cows, although more careful analysis suggested that the first cases of BSE probably occurred in the 1970s.[221,253] During the ensuing years, investigators have closed the circle of evidence, showing that vCJD represents the transmission of BSE to humans, presumably by ingestion of contaminated beef or byproducts from BSE-infected cattle.[72,125,220,223] These byproducts include many common household and medical products, such as gelatin in food products and in pharmaceutical capsules, bouillon cubes used for food preparation, and a wide variety of foodstuffs containing beef.

Although the origin of BSE is far from settled, most investigators concur that changes in the rendering of beef and sheep carcasses to remove fat for the preparation of meat and bone meal for use as a protein supplement in animal feeds led to the epidemic. Before the late 1970s, beef carcasses were heated and extracted with hydrocarbons such as chloroform to delipidate the homogenate.[33,83,231,251,253] Omitting the hydrocarbon-extraction step apparently decreased inactivation of bovine prions, thus allowing introduction of this agent into the food products of British cattle. The epidemic began slowly in cattle, with the first case documented in 1986; by the mid 1990s, more than 3,500 new cases of BSE were being reported each year. As a result of the BSE epidemic, 200,000 diseased cattle died as a result of BSE and nearly 4.5 million cattle were slaughtered preemptively, at a cost of approximately 4 billion English pounds, to curtail the epidemic.[5,49,221,258] BSE has been documented in U.S. herds, resulting in a ban of exportation of beef to several economically important markets.[206] As noted earlier, transmission to humans was suggested first in 1995 after the findings of CJD in three young adults were reported; and by 1996, additional cases of CJD in young adults were thought to be secondary to transmission from exposure to beef from BSE-infected cows.[72] Of the initial 20 human cases, only one individual was older than

40 years, and the mean age of infected humans was 28 years.[6,195,240,243,260] Additional evidence from in vitro studies of the protein agents responsible for BSE and vCJD and from animal inoculation indicated that vCJD represented a human infection with the agent responsible for BSE.[52,76,124,154] Because the BSE epidemic was recognized first in 1985, researchers argued that the incubation period is approximately 10 years. On the basis of studies in kuru and experimental animal models of TSE, this estimate was determined to be dependent on exposure, genetic susceptibility, and as yet other unrecognized risk factors.[61,160] For this and other reasons, mathematical projections of the extent of the human epidemic have been based on theoretical estimates of exposure rates, possible dose-dependent incubation periods, and as yet undefined host genes that may alter susceptibility to TSE. Even though most of these variables cannot be quantified, arguments have been put forth that the epidemic in humans has peaked and the 120 or so cases of vCJD that have resulted from contaminated beef will be the extent of human disease associated with BSE.[102,243] In contrast, other models of the current data suggest that as many as 100,000 people may be affected. Perhaps the most compelling argument against such a large number of human cases has been the slowly evolving epidemic of vCJD in humans, with the number of new cases declining, although several investigators have contested this hypothesis.[70,102,243,252]

PATHOLOGY AND PATHOGENESIS

Although the histopathologic features of TSE have been described well, the pathogenesis of these diseases remains unknown and the nature of the etiologic agent continues to evoke controversy. The initial claim that TSE resulted from a transmissible protein was met with considerable skepticism both because a paradigm of biology was challenged and because key elements of the supporting scientific data were incomplete. The vast majority of experimental studies have been performed with the agent responsible for scrapie in sheep, which had been adapted for growth in mice and other small animals. Early studies that argued that the scrapie agent did not contain a nucleic acid were based on studies with ultraviolet radiation inactivation of the agent. An important note is that these studies did not exclude the possibility that the scrapie agent contained nucleic acid but instead argued that if it contained nucleic acids, the coding sequence was so limited that it could not encode any replicative functions.[16,17,194] In fact, later calculations based on inactivation by gamma rays suggest that the scrapie agent could contain between 2- and 4-kilobase pairs of DNA.[208] Other experiments demonstrated that the infectivity of the scrapie agent could be eliminated or significantly reduced by treatment with agents that denatured proteins, such as guanidine hydrochloride, sodium hypochlorite (bleach), and proteases.[194] Together, these data led several groups of investigators to postulate that the agent is an infectious protein.[24,113,197] Prusiner and coworkers[187] isolated an infectious fraction from a scrapie-infected hamster brain homogenate and obtained partial amino acid sequence. This fundamental finding led to the identification of the prion (PrP^c) and eventually the finding that a cellular gene, *PRNP*, present on chromosome 20, encoded the transmissible agent responsible for the development of scrapie in mice and hamsters.[13,66] Not all investigators have been convinced that the scrapie agent is an infectious protein, and recently published data have been cited as evidence that it is a small virus.[168,169] Once the protein encoded by the *PRNP* gene had been identified and definitively linked to scrapie and other TSE, many investigators thought that the pathogenesis of these diseases would be elucidated quickly. However, the pathogenesis of these diseases remains uncertain, perhaps because of the inability to assign a function to the normal protein product, PrP^c. The conformation of the normal cellular form of PrP^c is primarily α-helical and is susceptible to protease digestion. Various functions have been proposed for the normal nonpathogenic isoform of the cellular PrP^c, yet transgenic mice lacking the gene encoding PrP^c have a normal life span and exhibit only minor variations in normal sleep patterns.[54,55,79,198] Most interestingly, these mice are completely resistant to prion disease regardless of the source of exposure, a finding that is consistent with the hypothesis that PrP^c is necessary for the disease process associated with scrapie and other TSE.[1,54] In contrast to the normal cellular form of PrP^c that is composed of four α-helical domains, the pathogenic form of PrP^{sc} (scrapie prion protein) exists in an extended beta sheet, is insoluble, and is partially resistant to protease digestion (PrP protease resistant [PrP^{res}]). The partial resistance of PrP^{res} to proteinase K digestion is a characteristic that allows pathogenic prions to be detected in tissue specimens and has been widely used to identify products of the conversion reaction of PrP^c to PrP^{res}.[174,213] The conversion of PrP^c to PrP^{res} represents a central paradigm of the prion hypothesis and is thought to occur either as the result of a process similar to the nucleation of crystal formation by seeding the normal cellular pool of PrP^c with PrP^{res} or, alternatively, as the result of a template-directed misfolding of a normal cellular protein. Thus, PrP^{res} can be viewed as a transmissible, infectious agent that catalyzes the conversion of the normal cellular protein to a form associated with protein deposition in the CNS, cell death, and, eventually, clinical disease in the host.

The normal cellular protein, PrP^c, is a small membrane glycoprotein that is covalently linked to cellular membranes, including the plasma membrane, by a glycosyl phosphoinositol (GPI) linkage.[225-227] This cell surface form can be released by treating cellular membranes with phospholipases.[225] In addition, a secreted form of the protein also is expressed. Genetic mutations in the cellular PrP^c gene appear to predispose the protein to assume other topologies, including a transmembrane form.[116,236] Membrane-associated forms are postulated to play an important role in the neurodegeneration associated with the accumulation of the misfolded forms of PrP^c, and secreted forms can accelerate disease in a genetically susceptible animal.[116,200] Chesebro and coworkers[65a,67,228a] demonstrated that transgenic mice encoding a GPI-anchorless form of PrP^c could generate an abnormal protease-resistant PrP^{res} that could be

transmitted to other animals and induce formation of amyloid plaques but failed to cause clinical spongiform encephalopathy (scrapie equivalent in mice) in experimental animals. Interestingly, when the anchorless form was coexpressed with the wild-type form of PrP^c, accelerated disease was seen. Thus, it appears that a cell surface–linked PrP^c is required for induction of disease yet that amyloid-like deposits can be formed from the secreted form of PrP^c and disease can be induced when both secreted and wild-type PrP^c are expressed.[67] Consistent with this observation has been the description of a transmissible PrP^c amyloid disease without spongiform encephalopathy after inoculation of tissue containing amyloid deposits from a patient with GSS without CNS spongiform degeneration.[193,200] Together, these studies argue that PrP^c misfolding, protease resistance, and amyloid formation are sufficient to confer transmissibility to the PrP^{res} but that these characteristics in themselves may not be directly responsible for transmissible disease. The challenge to existing paradigms of molecular biology and genetics, including the self-replication of a protein, were quickly noted by investigators in this field. Importantly, several investigators previously demonstrated that distinctive strains of the scrapie agent exist and that these strains induce definable and reproducible phenotypes of disease in experimental animals.[18,28,50,51,143] These well-accepted and reproducible studies strongly argued for the presence of a genetic program in the scrapie agent that was most consistent with a nucleic acid–containing agent. More recently, several studies have suggested that the phenotypic behavior of scrapie strains may be entirely dependent on the pathogenic conformation that the PrP^c assumes when it is exposed to pathogenic forms of PrP^c, which in turn is dependent on its posttranslational modifications.* Thus, researchers argued that the phenotypes of scrapie strains are entirely dependent on the protein structure of PrP^c and independent of any nucleic acid–encoded genetic trait. A second characteristic of etiologic agents of TSE that was difficult to ascribe to an infectious protein is the species barrier for transmission of prions between species. This phenotypic characteristic was noted when the scrapie agent from sheep was first adapted to mice and subsequently to other species, including hamsters. Other examples of a species barrier include BSE, in which 1000 lethal doses (as defined in cattle) must be given to a mouse to induce disease.[249] Interestingly, the species barrier not only contributes to the absolute resistance of species to infection with prions derived from other species but also can lengthen the mean incubation period in a population. The species barrier often is invoked to explain the rarity of TSE, even in populations repeatedly exposed to TSE in other species (e.g., humans exposed to scrapie-infected sheep), and possibly the relatively low number of human cases of vCJD that develop after exposure to beef contaminated with BSE.[72] A more worrisome aspect of the phenomenon of species barrier is that subclinical infections could result from exposure to BSE and subsequent transmission, leading to secondary cases with clinical symptoms.[123,243] A unifying explanation for the restriction of the transmission of prion disease between species that has been proposed argues that a species restriction is related to the efficiency with which exogenous prions interact with endogenous host-derived PrP^c to form PrP^{res}.* Although considerable gaps in the understanding of the infectious agent responsible for TSE persist and at times have contributed to the controversy that surrounds the infectious protein hypothesis, more recent in vitro studies have shifted the view of the field toward the infectious protein hypothesis. These studies include the findings that protease-resistant prions (PrP^{res}) that appear identical biochemically to PrP^{res} derived from infected brain can be produced in cell-free systems in vitro.[1,59,149] However, until recently, these preparations could not transmit disease to uninfected animals unless they were supplemented with brain tissue derived from diseased animals, presumably because their titer was too low.[121] A more recent study using a system to amplify prion production through sequential folding, sonication, and feeding of new substrate produced titers of in vitro–derived prions that could transmit TSE to susceptible animals and accelerate the development of symptoms in infected animals.[58] The results from this in vitro system have provided compelling evidence for a mechanism of recruitment of cellular proteins by a misfolded protein and subsequent protein deposition as an etiology of diseases classified as TSE.

Although several mechanisms can be envisioned to explain how a misfolded host protein can lead to the recruitment and misfolding of additional copies of the protein, how the deposition of PrP^{res} can lead to disease remains unclear. Based on solid-state nuclear magnetic resonance and x-ray crystallography, the underlying structure of prion amyloids appear to share common structural features and single molecular methods will continue to advance our understanding of misfolding and aggregation.[153] The loss of normal protein function and the development of disease in humans have several well-studied examples, such as cystic fibrosis.[111,256] These diseases are associated with loss of function of an essential cellular protein. In contrast, the accumulation of cellular proteins, such as amyloid secondary to overproduction of a normal protein, can lead to disease and usually is associated with deposition and loss of organ function. In the case of TSE, the proposed mechanism for the generation of pathogenic prions appears fundamentally different in that the conformational change from a predominance of α-helical structure of PrP^c to molecules containing extensive amounts of an extended β sheet, PrP^{res}, results in the accumulation of insoluble, protease-resistant proteins that can recruit additional normal cellular proteins into this conformation. In vitro cell-free systems and studies from kindred with inherited TSE such as GSS and FFI have shown that exposure to the misfolded prion protein such as PrP^{res} can result in this conversion.† In genetic TSE such as GSS and FFI, the genetic mutation is inherited as an autosomal dominant trait, and, interestingly, the PrP^{res} pathogenic form of the prion protein has been shown to be derived from the mutant allele individual

*References 19, 59, 60, 229, 243, 244, 248.

†References 1, 59, 60, 63, 94, 207.

heterozygous for this allele.[1,59,63] The energetics required for the conversion in conformation of PrP^{c} to PrP^{res} are thought to be unfavorable and could require a mutant template or perhaps a chaperone protein (protein X).[59,141,149,233] Because the conversion reaction is essentially irreversible, this change in protein conformation results in the accumulation of the insoluble and protease-resistant PrP^{res} protein. Arguments have been put forth that certain conformations of PrP^{c} favor the conversion to pathogenic forms of PrP^{res}, thus providing additional constraints on the expression of disease that could explain the non-PrP^{c} genetic contributions to disease susceptibility and also provide a final common pathway for genetic and infectious forms of the disease.[1,236] Interestingly, several studies have argued that different protease fragments that are generated after PrP^{res} treatment with protease K may be associated with different patterns of disease in the CNS and thus provide additional diversity in disease phenotype attributed to this single, small protein.[189,190,243] Once the pathogenic PrP^{res} accumulates, additional newly synthesized molecules are converted into PrP^{res}, and clinical symptoms develop, depending on the site of cell loss in the CNS. Accumulation of the PrP^{res} isoform probably involves a combination of new synthesis of PrP^{res} and the decreased clearance of the misfolded aggregate. The failure in the clearance of the misfolded pathogenic isoform may ultimately be the major pathway leading to accumulation of PrP^{res} and disease.[1,212] Finally, studies have linked copper binding to the product of the PrP^{c} and oxidation of the prion protein.[1,30,204,216,257] Alternatively, a copper-containing prion complex localized to the synaptic junction could protect normal synapses from oxidants or perhaps play a direct role in copper metabolism or transport.[137,216] Loss of normal prion function by misfolding could then lead to neuronal loss. The importance of these newly described characteristics of PrP^{c} remains incompletely defined at this time.

Although inoculation of a susceptible host with prion-contaminated cadaveric growth hormone or the use of contaminated instruments during neurosurgical procedures clearly can transmit CJD, the route of infection leading to vCJD is only assumed to be through oral ingestion of contaminated beef, based on studies in non-human primates.[26,243] As noted earlier, studies have demonstrated that other TSE, including kuru, can be transmitted by oral ingestion of infectious material, but only ingestion of large inoculums and often requiring extended incubation periods.[103] In studies in mice, researchers have shown that 10 g of BSE-infected cow brain can infect and kill most mice.[11] Even though extrapolating from these data a comparable dose required for human infection will be difficult, these findings demonstrate that the BSE agent can be transmitted by oral ingestion.

The pathway leading from ingestion of PrP^{res} tissue to deposition in the CNS has been shown to require local replication in lymphoid tissue, which is thought to be followed by bloodborne dissemination to the CNS.[1,118,144,146] High titers of infectious prions can be found in the liver and the spleen as well as in lymphoid tissue such as the tonsils and other lymphoid tissue of the oropharynx and gut, suggesting that the titer of the infecting PrP^{res} is amplified in these tissues before spread to the CNS. In vCJD, PrP^{res} can be found in the tonsils at levels as high as 10 percent of the infected brain.[121,245] However, these findings were reported to be restricted to vCJD, reflecting a characteristic of the PrP^{res} of vCJD or possibly secondary to the route of inoculation. Studies in mice have demonstrated that performing splenectomy before inoculating with the scrapie agent can prolong the disease course, and subsequent studies have demonstrated the importance of replication in cells derived from bone marrow in neuroinvasion.[69,139,151] Other studies have demonstrated that expression of PrP^{res} in the peripheral nervous system is sufficient to transmit disease, suggesting that direct hematogenous dissemination to the brain is not necessary for transmission of TSE.[201] Prions are thought to replicate in these tissues before spreading to the CNS, and a study documented the presence of PrP^{res} in the appendix of an individual that was removed 8 months before the onset of TSE.[121] Investigators once thought the B lymphocytes represented a likely candidate for the cell transmitting the PrP^{res} to the CNS; however, studies have provided data inconsistent with this mechanism of transmission.* Studies have provided evidence for the role of follicular dendritic cells in lymphoid tissue as sites of prion replication and may direct the prion to the CNS.[139,151] Other investigators have suggested that host cell molecules as yet unidentified may provide the necessary interactions with the prion molecule, which permits their trafficking with migratory myeloid cells and, ultimately, entry into the CNS.[162a] Candidate molecules included components of the complement system based on the study of PrP^{res} in transgenic mice lacking specific components of the complement system, perhaps secondary to the expression of Fcγ and complement receptors CD21/CD35 by follicular dendritic cells.[21,147,162]

The pathologic findings of TSE include the hallmark of a triad of histologic findings: (1) neuronal loss, (2) proliferation of reactive astrocytes, and (3) status spongiosis.[15] *Status spongiosis* is a descriptive term of degeneration of neurons and collapse of the cortical cytoarchitecture leading to vacuolation of the neuropil.[15] Amyloid plaques also are observed in some patients, and in some cases PrP^{res} is present in these plaques.[15,53,145] Whether the distribution of spongiform lesions is related to the pathogenesis of these disorders or merely reflects the duration of disease before the onset of clinical symptoms is unknown; however, some TSE, such as FFI, exhibit a preponderance of histopathologic changes in specific locations, such as the thalamus.[15,53,165,188,234] Recent descriptions of the neuropathologic process of vCJD have suggested that distinctive histopathologic changes may be present in the cases thus far studied[243] and include a distinctive plaque containing a central amyloid core and fibrillary periphery with extensive spongiform changes in the immediate periphery of the plaque.[91,135] The surrounding spongiform changes are proximal to the plaque, and the remaining neuropil is relatively intact.[53,135] These findings are unique to vCJD cases and are not seen in sporadic CJD cases from outside Great Britain.[52,136] Histopathologic lesions in the cerebral and cerebellar

TABLE 192-2 **Human Transmissible Spongiform Encephalopathies**

Disease	Acquisition	Clinical Features
Kuru	Ingestion of or percutaneous inoculation with contaminated central nervous system tissue during ritual cannibalism in Fore tribe in New Guinea	Bimodal age distribution with disease in adolescents and in older adults Adolescents presented with ataxia and dementia with prominent cerebellar involvement
	Last case reported in 1985	Rapidly progressive disease
Creutzfeldt-Jakob disease (CJD)	Sporadic cases account for 85% of reported cases of CJD; approximately 15% are secondary to defined mutation in PrP^c, and an unknown number are secondary to infection	Classic presentation of dementia and sensory abnormalities followed by loss of motor functions
	Well-documented cases after neurosurgical procedures and injection of cadaveric growth hormone	Rapid progression of symptoms with death usually occurring <1 year of onset Disease of late middle age except in cases acquired after iatrogenic transmission
Variant Creutzfeldt-Jakob disease (vCJD)	Acquired through exposure to beef or beef byproducts contaminated with bovine spongiform encephalopathy	Presentation similar to CJD but disease progresses more slowly, with death occurring >12 months after symptoms develop
	Route of acquisition unknown but presumed to be oral	Mean age of cases approximately 28 years, with documented cases in adolescents
Gerstmann-Sträussler-Scheinker syndrome (GSS)	Autosomal dominant inheritance with documented point mutations in PrP^c gene	Disease of middle age, with mean age at onset of 45 years
		Motor abnormalities and progressive dementia
Familial fatal insomnia (FFI)	Autosomal dominant inheritance with point mutations in PrP^c gene (missense mutation codon 178)	Disease of middle age Presentation includes insomnia, dysautonomia, and motor dysfunction
Sporadic fatal insomnia	No genetic mutations identified, but homozygosity at methionine 129 characteristic	Presentation similar to FFI and neuropathologic changes similar

cortices, basal ganglia, thalamus, and brain stem also have been described.[136] Involvement of the cerebellum appears to be more common in vCJD than in reported cases of sporadic CJD, but this finding may be related to the differences in the age at onset of disease in these two populations, because recent findings from young patients with sporadic CJD have suggested that these patients have a syndrome more closely resembling vCJD than sporadic CJD in older patients.[23] Extensive widespread CJD findings that included involvement of cerebellar white matter, corticospinal degeneration, and ballooned neurons, were also reported in an 11-year old who died of CJD after treatment with native human growth hormone.[178] Last, electron microscopic studies of plaques from vCJD brain tissue have suggested subtle but recognizable differences between plaques obtained from patients with vCJD and CJD.[91,94]

CLINICAL MANIFESTATIONS

Only the clinical manifestations of sporadic CJD and vCJD are discussed; other TSE, such as GSS and FFI, are diseases that are unlikely to be encountered in children (Table 192-2). The interested reader is referred to discussions of these diseases in adults.* Clinical signs and symptoms during the early stages of CJD are subtle and often complex and include both motor and sensory dysfunction.[126] Abnormalities in gait and vision and complaints of headache, dizziness, and paresthesias often are noted.[39,48,185,209] Intellectual dysfunction, including loss of memory, speech abnormalities, anxiety, and depression, also are often presenting complaints of patients with early stages of CJD.[23,39,48] Neurologic abnormalities may include corticospinal tract dysfunction as manifested by hyperreflexia, spasticity, and extensor plantar reflexes. Visual disturbances include visual field abnormalities and, in some cases, cortical blindness. Seizures are not a frequent clinical symptom of patients with CJD. Other less frequent findings include evidence of autonomic system dysfunction and, rarely, lower motor neuron disease.[185,214] Although death secondary to complications associated with the vegetative state usually occurs within 1 year of onset of symptoms, a small percentage of patients may exhibit a prolonged disease course.[48]

The clinical symptoms of vCJD are distinct from those of sporadic CJD. This disease has been reported in an 11-year old child with neonatal growth hormone deficiency treated since infancy with injections of native human growth hormone, as well as an adolescent; therefore, CJD or vCJD could potentially be encountered by pediatricians.[178] The age range for reported cases of vCJD is 11 to 48 years, a distribution clearly outside that of sporadic CJD. Symptoms have included psychiatric and sensory disturbances, such as dysesthesias and paresthesias with electromyographic evidence of denervation. Psychiatric symptoms included anxiety, depression, anorexia, social withdrawal, and other nonspecific complaints. As the disease progressed, more familiar findings of TSE, including pyramidal tract dysfunction, rigidity, cerebellar dysfunction, and myoclonus, developed. Visual disturbances also were noted late in the disease. The duration of illness has exceeded 1 year in most patients with vCJD and follows complications associated with the

*References 39, 88, 98, 126, 161, 165.

vegetative state. As noted before, the clinical presentation of sporadic CJD in young individuals more closely resembles that of vCJD than of sporadic CJD in older individuals.[23]

DIAGNOSIS

The diagnoses of CJD and vCJD require a high index of suspicion and, in the case of vCJD, a history compatible with exposure to contaminated beef or beef byproducts or, possibly, a previous neurosurgical procedure, growth hormone injection, or corneal transplantation. Routine laboratory findings are nonspecific and not helpful. No consistent reports demonstrate systemic or CNS inflammation; thus, routine laboratory analysis of cerebrospinal fluid often is nondiagnostic.

Assays for specific cerebrospinal fluid proteins, such as the 14-3-3 protein, tau, or neuron-specific enolase, may provide helpful laboratory evidence of CJD or vCJD.* Definitive premortem diagnosis requires biopsy tissue, and histopathologic diagnosis can be facilitated by use of PrP^{res}-specific antibodies in both immunocytochemistry and Western blot assays.[8,53,243,245] The use of monoclonal antibodies specific for PrP^{res} has permitted a more thorough understanding of the distribution of prions in CNS and non-CNS tissue in patients with TSE. Hill and coworkers have reported that tonsillar biopsy followed by detection of PrP^{res} by both Western blot and immunocytochemistry or *PRNP* sequencing is useful for establishing the diagnosis of vCJD disease.[92,122] This approach has been particularly valuable for defining the incidence of vCJD infection in populations such as has been carried out in studies in Great Britain.[92,127] The National Prion Disease Pathology Surveillance Center† offers diagnostic testing assays for 14-3-3 and tau proteins in CSF, *PRNP* sequencing, Western blot analysis to identify and characterize PrP, as well as histologic processing of brain tissues, and expert neuropathologic consultation in patients suspected of having CJD.[99] More recently, in-vitro prion formation using CSF has been shown to be very sensitive and specific for the diagnosis of prion disease.[8a,173a,188a]

Imaging of patients with suspected prion disease has been extremely helpful in establishing the diagnosis of these rare diseases. Although computed tomography may reveal a variety of structural abnormalities, none is sufficiently specific to be considered diagnostic. In contrast, magnetic resonance imaging findings of increased T2 signals from the striatum and thalamus are specific for prion diseases, especially vCJD.[10,89] Abnormal signals originating from the pulvinar in the posterior thalamus ("pulvinar sign") are distinctive for vCJD and should be considered highly predictive for the disease.[10,71,164] Other studies have shown lesions in the cortex and basal ganglia, without involvement of the thalamus, in patients with biopsy-confirmed CJD.[177,235] Therefore, cortical signal increases, as well as hyperintensities in the basal ganglia and the thalamus, may all occur in patients with CJD.

Electroencephalographic tracings from patients with CJD and vCJD are characteristic but not diagnostic. The classic findings are synchronous, bilateral biphasic or triphasic periodic sharp waves of 1-cycle to 2-cycles per second on a background of generalized slowing. Repeat or serial tracings may be necessary to document these changes.[27,68,228]

TREATMENT

No known treatments of TSE are licensed for medical practice. In vitro models of PrP^{c} folding have suggested that a variety of agents may limit production of pathogenic forms of PrP^{res} in neuroblastoma cells in vitro. Comprehensive reviews of treatment modalities have been published, and the interested reader is referred to these publications.[57,238] Derivatives of Congo red, polyene antibiotics related to amphotericin B, branched polyamines, and phenothiazines all have been reported to exhibit some activity and to delay onset of disease in experimental animals.[238] To date, no evidence that any of these proposed therapies would be effective in human TSE has been reported. Interestingly, at least two reports have suggested that anti-prion antibodies may offer a therapeutic approach to TSE. These reports suggested that anti-prion antibodies directed at cell surface PrP^{c} prevented infection of susceptible cells and also eliminated infection in a chronically infected cell line.[86,192,250] These findings argued that impaired clearance of misfolded PrP^{c} contributed to disease in animals infected with PrP^{res} and that passive antibody therapy could potentially cure similar infections in vivo. Treatment of mice with soluble lymphotoxin-β blocked follicular dendritic cell maturation and inhibited the development of scrapie in inoculated, susceptible mice, suggesting that interventions with agents that can block neuroinvasion may be efficacious.[163,183] Small molecules that target protein misfolding are in preclinical development.[100,219]

PREVENTION

Because effective treatments of TSE remain as yet undefined, prevention of disease remains the goal of current medical practice. Infection that occurs after exposure during neurosurgical procedures (including dural grafts and stereotaxic electrodes), exposure to contaminated CNS tissue in the form of growth hormone or gonadotropic hormone preparations, and corneal grafts are well-known modes of transmission of TSE that are preventable in most cases. Because transmissions by blood and blood products have been reported, the American Red Cross has placed restrictions on donors to exclude those who may have been exposed to agents associated with TSE (see earlier discussion). Cases of TSE that follow exposure to human feces, urine, or mucosal secretions have not been reported; therefore, current universal precautions employed in health care settings should suffice to prevent health care–associated transmission during routine care of the patient with TSE. The inactivation of tissue and fluid suspected of being contaminated with

*References 109, 110, 134, 152, 215, 261.

†National Prion Disease Pathology Surveillance Center website: http://www.cjdsurveillance.com.

prions is problematic. Early studies indicated that subjecting prion-containing brain tissue to temperatures in excess of 360°C resulted in only approximately a 90 percent reduction in infectivity.[34,46] In addition, CJD has been transmitted from paraffin-embedded tissue sections.[43,44] Several different approaches for decontamination of prion-contaminated tissue and instruments have been proposed.[167,205,210] Tissues, such as brain, eyes, and spinal cords from infected patients, may have high levels of infectivity. Therefore the tissues and instruments in contact with these tissues should be handled as biohazardous materials. Instruments should be cleaned with high concentrations of sodium hydroxide or undiluted sodium hypochlorite and then autoclaved at high temperatures for prolonged periods of time, or, if practical, incinerated. Suffice it to say that the concentration of prions in lymphoid and nervous tissue should be emphasized to anyone in contact with patients with TSE, and material that may be contaminated with prions should be handled in a rigorous manner to ensure safe disposal. To date, no cases of transmission after routine dental procedures have been reported. Genetic counseling may be helpful in familial disease in families with a *PRNP* mutation.[140] There is no vaccine available against prion disease.

CHLAMYDIA

CHAPTER 193

Chlamydia Infections

Margaret R. Hammerschlag • Stephan A. Kohlhoff

Chlamydiae are obligate intracellular pathogens that have established a unique niche within the host cell. They cause a variety of diseases in animal species at virtually all phylogenic levels. In 1999, Everett and colleagues[40,46] reported a taxonomic analysis involving the 16S and 23S rRNA genes that found that the order Chlamydiales contained at least four distinct groups at the family level and that within the family Chlamydiaceae there were two distinct lineages; they suggested splitting of the genus *Chlamydia* into two genera, *Chlamydia* and *Chlamydophila*. This classification was not universally accepted, and recently it was agreed that the family Chlamydiaceae contains a single genus, *Chlamydia*.[58] This position has been supported by additional data on *Chlamydia* genome sequences. The genus *Chlamydia* now contains nine recognized species: *C. trachomatis*, *C. psittaci*, *C. pneumoniae*, *C. pecorum* (infects cattle, other ruminants, and koalas),[40,46] *C. muridarum* (formerly the agent of mouse pneumonitis), *C. suis* (an important pathogen of swine), *C. abortus* (causes abortion in cattle and sheep; rarely has caused abortion in humans), *C. caviae* (formerly *C. psittaci* guinea pig conjunctivitis strain), and *C. felis* (causes epidemic keratoconjunctivitis in cats). *C. trachomatis* and *C. pneumoniae* are the most significant human pathogens, and *C. psittaci* is an important zoonosis.

Recently, several chlamydia-like organisms that are endosymbionts of free-living amoebae have been identified.[59] These organisms, which include *Parachlamydia acanthamoebae*, *Simkania negavensis*, and *Neochlamydia hartmannellae*, have been termed *environmental chlamydiae*.[59,100] Analyses of nearly full-length 16S rRNA gene sequences of these isolates showed that they clustered with other members of the order Chlamydiales but in a lineage separate from those of *Chlamydia* (16S rRNA sequence similarities >88%). Data on the potential role of these organisms in human disease are limited. This bacteria–protozoa interaction might have been a driving force for the development of effective mechanisms by bacteria to survive phagocytosis by unicellular eukaryotes, which in turn may have been a first step in the evolution of intracellular bacterial pathogens of higher organisms.[32,123]

Chlamydiae are characterized by a unique developmental cycle with morphologically distinct infectious and reproductive forms—the elementary body and the reticulate body. They have a gram-negative envelope without detectable peptidoglycan, although recent genomic analysis has revealed that both *C. trachomatis* and *C. pneumoniae* encode proteins forming a nearly complete pathway for the synthesis of peptidoglycan, including penicillin-binding proteins.[85,122,124,136] This finding is the basis for the so-called chlamydial peptidoglycan paradox, given that it has been known for decades that chlamydial development is sensitive to β-lactam antibiotics.[122] Chlamydiae also share a group-specific lipopolysaccharide (LPS) antigen and use host adenosine triphosphate (ATP) for the synthesis of chlamydial protein.[136] Although chlamydiae are auxotrophic for three of four nucleoside triphosphates, they encode functional glucose-catabolizing enzymes that can be used for the generation of ATP. As with peptidoglycan synthesis, for some reason these genes are turned off.[136] All chlamydiae also encode an abundant protein, the major outer membrane protein (MOMP or OmpA), that is surface exposed in *C. trachomatis* and *C. psittaci* but apparently not in *C. pneumoniae*.[136] MOMP is the major determinant of the serologic classification of *C. trachomatis* and *C. psittaci* isolates.

After infection develops, the infectious elementary bodies, which are 200 to 400 μm in diameter, attach to the host cell by a process of electrostatic binding and are taken into the cell by endocytosis that does not depend on the microtubule system. Within the host cell, the elementary body remains within a membrane-lined phagosome. The phagosome does not fuse with the host cell lysosome. The inclusion membrane is devoid of host cell markers, but lipid markers traffic to the inclusion, which suggests functional interaction with the Golgi apparatus. The elementary bodies then differentiate into reticulate bodies that undergo binary fission. After approximately 36 hours, reticulate bodies differentiate into elementary bodies. At approximately 48 hours, release may occur by cytolysis or by a process of exocytosis or extrusion of the whole inclusion, with the host cell left intact. Chlamydiae also may enter a persistent state after treatment with certain cytokines such as interferon-γ, treatment with antibiotics, or restriction of certain nutrients. In the persistent state, metabolic activity is reduced. The ability to cause prolonged, often subclinical infection is one of the major characteristics of chlamydiae.[70]

INFECTIONS CAUSED BY CHLAMYDIA TRACHOMATIS

Epidemiology

C. trachomatis infection is the most prevalent sexually transmitted infection (STI) and infectious disease in the

United States today.[26-28] In 2010, over 1.3 million were reported to the Centers for Disease Control and Prevention (CDC).[27,28] The prevalence of chlamydial infection is associated less with socioeconomic status, urban or rural residence, and race or ethnicity than is the case with gonorrhea and syphilis. Infection with *C. trachomatis* tends to be asymptomatic and of long duration. If a pregnant woman has active infection during delivery, the infant may acquire the infection and, as a consequence, either conjunctivitis or pneumonia.[26,44,71,73,141] Children also may acquire chlamydial infection as a result of sexual abuse.

Chlamydia Trachomatis Infections in the Neonate

History

At the beginning of the 20th century, before expectant mothers began being screened for sexually transmitted diseases (STDs), the term *ophthalmia neonatorum* was, for all practical purposes, synonymous with gonococcal conjunctivitis. As neonatal conjunctivitis came under control with silver nitrate prophylaxis, the importance of another form of ophthalmia neonatorum, *inclusion blennorrhea*, was noted. The relationship between maternal genital infection and conjunctivitis of the newborn associated with inclusion bodies within epithelial cells was established by Thygeson and Stone in 1942.[150] Respiratory infection in infants caused by *C. trachomatis* probably was reported first in 1941 by Botsztejn,[21] who described an entity that he called *pertussoid eosinophilic pneumonia*.

Epidemiology

The rate of cervical infection with *C. trachomatis* during pregnancy varies from 1 to 37 percent, with the highest rates occurring in women 25 years of age and younger. *C. trachomatis* infection is acquired by the infant from the mother during parturition, as demonstrated in multiple well-controlled prospective studies conducted in the 1970s and 1980s of maternal–infant infection in which infection occurred only in infants born to infected mothers.[26,44,71,63,141] No convincing evidence demonstrates horizontal transmission from mother to infant, from other family members to the infant, or from infant to infant after delivery. Infection after cesarean delivery, usually associated with rupture of the membranes, or infection through intact membranes is a rare event but may occur.[12] The overall risk for an infant born to a mother with active chlamydial infection becoming infected at any anatomic site has been reported to be approximately 50 to 75 percent in various studies (Table 193-1).[44,73,141] Infants can be infected at more than one site, including the conjunctiva, nasopharynx, rectum, and vagina. The most frequent clinical manifestation of neonatal chlamydial infection, inclusion conjunctivitis, has been reported to occur in 15 to 37 percent of infants born to mothers with untreated cervical chlamydial infection.[44,73,141] The most frequent site of infection, however, is the nasopharynx, with 78 percent of infected infants having positive nasopharyngeal cultures in one study.[61] Approximately half of infants with inclusion conjunctivitis also will be infected in the nasopharynx. In only a minority of infants with nasopharyngeal infection does chlamydial pneumonia eventually develop; Hammerschlag and colleagues[71] found that pneumonia subsequently developed in only 4/12 (33%) infants with isolated nasopharyngeal infection. The overall risk for pneumonia developing in infants born to chlamydia-positive mothers has been reported to range from 1 to 22 percent.[44,73,141]

Data on the risk for acquiring rectal or vaginal infection are more limited. Bell and colleagues[13] demonstrated that perinatally acquired *C. trachomatis* infection may persist for months to more than 2 years. Twenty-two infants born to women with culture-documented chlamydial infection were monitored, and positive cultures from the nasopharynx and oropharynx in the infants were detected as late as 28.5 months after birth. Rectal and vaginal infections were asymptomatic and persisted for at least 1 year, which can become an important confounding

variable when young children are tested for the presence of *C. trachomatis* during evaluation for suspected sexual abuse.

Conjunctivitis. *C. trachomatis* was the most frequent identifiable infectious cause of neonatal conjunctivitis, and conjunctivitis was the major clinical manifestation of neonatal chlamydial infection in the United States in the 1990s. The introduction of systematic screening and treatment of pregnant women has resulted in a dramatic decrease in the number of perinatal chlamydial infections, including conjunctivitis, in the United States.[1,62] However, in countries in which pregnant women are not screened routinely, including many developing countries, *C. trachomatis* remains the most frequent cause of neonatal conjunctivitis.* The incubation period of *C. trachomatis* conjunctivitis is 5 to 14 days after delivery or earlier if premature rupture of membranes has occurred. At least 50 percent of infants with chlamydial conjunctivitis also will have nasopharyngeal infection. The manifestation is extremely variable and ranges from mild conjunctivitis with scant mucoid discharge to severe conjunctivitis with copious purulent discharge, chemosis, and pseudomembrane formation. The conjunctiva can be very friable and may bleed when stroked with a swab. Eyelid erythema and edema frequently are present. A Gram-stained conjunctival smear initially may reveal a predominance of polymorphonuclear leukocytes. Chlamydial conjunctivitis needs to be differentiated from gonococcal ophthalmia in some infants, especially those born to mothers who did not receive any prenatal care, had gonorrhea during pregnancy, or abused drugs. An overlap in both incubation periods and clinical findings can occur. Bilateral infections are present in two thirds of cases. A follicular reaction is not seen because infants younger than 3 months of age do not have the requisite lymphoid tissue present in the conjunctiva.

Pneumonia. As stated previously, approximately 70 percent of infected infants will have positive nasopharyngeal cultures, but the majority of these infections are asymptomatic.[71,138] Chlamydial pneumonia develops in only approximately 30 percent of infants with nasopharyngeal infection.[71] In infants in whom pneumonia does develop, the manifestations and clinical findings are very characteristic.[10,77,151] The children usually are seen initially when they are between the ages of 4 and 12 weeks. A few cases have been reported in infants as young as 2 weeks of age, but no cases have been seen in infants older than 4 months. The infants frequently have a history of cough and congestion, with an absence of fever. On physical examination, the infant is tachypneic, and rales are heard on auscultation of the chest; wheezing is a distinctly uncommon finding.[10,77,151] No specific radiographic findings except hyperinflation are found (Fig. 193-1). Significant laboratory findings include peripheral eosinophilia (>300 cells/cm^3) and elevated serum immunoglobulins. If cultures are performed, infants with *C. trachomatis* pneumonia may remain symptomatic and shed the organism from the nasopharynx for protracted periods.[13,62] Generally, infantile pneumonia caused by *C. trachomatis* appears to be self-limited. Most infants can be managed as outpatients, although a few cases of severe disease requiring hospitalization and assisted ventilation have been reported. *C. trachomatis* pneumonia in infants also appears to be associated with few sequelae, although data are limited. Rarely, infants with *C. trachomatis* pneumonia may have concomitant otitis media.[151]

FIGURE 193-1 ■ Anteroposterior chest radiograph of a severely ill 1-month-old male infant with *Chlamydia trachomatis* pneumonitis. Diffuse interstitial infiltrates and hyperaeration with a flattened diaphragm are prominent.

Diagnosis of *Chlamydia trachomatis* Infection in Infants

The diagnosis of neonatal conjunctivitis cannot be made on clinical grounds alone. Significant overlap in both incubation period and clinical findings occurs with infections by other organisms, especially *Neisseria gonorrhoeae*. In a high-risk population, particularly infants born to women with no prenatal care, gonococcal ophthalmia must be considered seriously.[73] The incubation period for gonococcal conjunctivitis is usually 3 to 5 days, but it can be longer. The incubation period for chlamydial conjunctivitis is approximately 5 to 14 days. Most cases will be evident by the time the infant is 2 weeks of age, which is after the infant leaves the hospital. Epidemiologic clues can help the physician decide whether gonococcal ophthalmia needs to be considered. Hammerschlag and

*References 116, 132, 137, 156, 160, 161.

colleagues[63,73] noted that seven of the eight infants with gonococcal conjunctivitis were born to mothers who had not received prenatal care. Five of these women were abusers of crack cocaine. Another epidemiologic clue is a history of gonorrhea or other STD during pregnancy. The clinical manifestation of *C. trachomatis* pneumonitis in infants is fairly characteristic, and clinical diagnosis may be established with a degree of certainty.

The gold standard for diagnosis of *C. trachomatis* infection in infants and children remains isolation of *C. trachomatis* by culture from the conjunctiva, nasopharynx, vagina, or rectum. There are currently three U.S. Food and Drug Administration (FDA)-approved, commercially available nucleic acid amplification tests (NAATs) for the diagnosis of *C. trachomatis* infection (described in detail in the discussion on infection in older children and adolescents). None are currently approved for use in children. However, available data suggest that NAATs are equivalent to culture for detection of *C. trachomatis* in the conjunctiva and nasopharynx of infants with conjunctivitis.[75,161]

Treatment of Chlamydial Conjunctivitis and Pneumonia in Infants

Oral erythromycin suspension (ethylsuccinate or stearate) 50 mg/kg/day for 14 days is the therapy of choice for the treatment of chlamydial conjunctivitis and pneumonia in infants.[11,26,62] It provides better and faster resolution of the conjunctivitis, in addition to treating any concurrent nasopharyngeal infection, which prevents the development of pneumonia. Additional topical therapy is not needed. The efficacy of this regimen has been reported to range from 80 to 90 percent; however, as many as 20 percent of infants may require another course of therapy.[11,62] Erythromycin given at the same dose for 2 weeks is the treatment of choice for pneumonia and results in clinical improvement and elimination of the organism from the respiratory tract.

Treatment with oral erythromycin has been associated with hypertrophic pyloric stenosis in infants younger than 6 weeks of age who were given the drug for prophylaxis after nursery exposure to pertussis.[33,81] Erythromycin is a motilin receptor agonist. Data on the use of other macrolides, including azithromycin or clarithromycin, for the treatment of neonatal chlamydial infection are limited. No studies of clarithromycin have been published; only one small study evaluated azithromycin and found that a short course of azithromycin suspension 20 mg/kg/day orally, one dose daily for 3 days, was as effective as was 2 weeks of erythromycin for eradication of *C. trachomatis* from the conjunctivae and nasopharynx of infants with conjunctivitis.[66,74]

Prevention and Control Strategies

Because *C. trachomatis* infections are transmitted vertically from mother to infant during delivery, several possible options for intervention exist. Prospective studies of mother-to-infant transmission of *C. trachomatis* have demonstrated that neonatal ocular prophylaxis with silver nitrate, erythromycin, or tetracycline ophthalmic ointment does not prevent the development of chlamydial conjunctivitis.[29,73] The most effective method of control of perinatal *C. trachomatis* infection is screening and treatment of pregnant women.[62,65,114] In the 1980s, McMillan and colleagues[111] and Schachter and coworkers[142] reported that treatment of pregnant women infected with *C. trachomatis* with erythromycin resulted in a dramatic decrease in chlamydial infection (i.e., conjunctivitis and nasopharyngeal infection) in their infants in contrast to infants born to untreated infected women. The introduction of NAATs for diagnosis and the use of well-tolerated antibiotic regimens, including amoxicillin and single-dose azithromycin, have increased the efficacy of prenatal screening and treatment.[26] This approach has been validated by a dramatic decrease in perinatal chlamydial infection in the United States[62,72] and persistence of these infections in countries in which screening and treatment of pregnant women are not standard practice, such as the Netherlands, Ireland, India, and China.[116,132,137,156,160] Rours and colleagues[137] reported that from 1996 through 2001, *C. trachomatis* was responsible for 61 to 64 percent of cases of neonatal conjunctivitis seen in a large university-affiliated hospital in Rotterdam. Even though the rate of *C. trachomatis* infection among pregnant women in Rotterdam exceeded 5 percent, prenatal screening and treatment are not part of routine prenatal care in the Netherlands.

Reasons for failure of maternal treatment to prevent infantile chlamydial infection include poor compliance and reinfection from untreated or new sexual partners. Even with effective screening, some infected women will be missed, depending on the methods used. Additionally, some women do not seek prenatal care.

Infections in Older Children

C. trachomatis has not been associated with any specific clinical syndrome in older infants and children. Most attention given to *C. trachomatis* infection in these children has concentrated on its relationship to sexual abuse. Isolation of *C. trachomatis* from a rectal or genital site in children without previous sexual activity may be a marker of sexual abuse; moreover, evidence for other modes of spread, such as through fomites, is lacking for this organism.[26,63,65,83-86] Perinatal maternal-to-infant transmission resulting in vaginal or rectal infection has been documented, with prolonged infection lasting for periods up to 3 years.[13,139,141] This duration can be an important confounding variable in evaluation of possible sexual abuse in a young child.

Four studies examining the epidemiology of STIs in children and adolescents being evaluated for suspected sexual abuse have been published since 2005. Three were retrospective chart reviews, including one each from Vienna, Austria,[93,95] Auckland, New Zealand[90,92] and Miami, Florida.[143] Despite differences in population and methodologies,[143,145] the results of the retrospective studies were fairly consistent. Charts were examined from a total of 4350 children, who were seen over periods

ranging from 4 to 7 years. The ages ranged from 0 to 17 years, and the overwhelming majority were girls. The prevalence of STIs, specifically gonorrhea and *C. trachomatis*, was low, ranging from 0.4 to 1.8 percent. These findings are consistent with earlier published studies.[37,83-86] Because these were retrospective chart reviews, they had some major limitations. Inclusion criteria varied, and not every child or adolescent was tested for every STI. In the one prospective study, Giradet and colleagues[51,52] examined children 0 to 13 years of age being evaluated for suspected sexual abuse or assault at seven tertiary care centers in the United States (in Houston, Tex, Atlanta, Ga, Harrisburg, Pa, and New York City). All children were tested at multiple sites for *N. gonorrhoeae* and *C. trachomatis* by culture. Vaginal and urethral swabs and urine were also tested using two NAATs. A total of 536 children were enrolled, 485 (90.5%) were girls. None of the 51 boys enrolled were positive for an STI. Overall, 40 (8.2%) of the girls were found to have one or more STIs. *C. trachomatis* was detected by culture and/or NAAT in 15 (3.1%) of the girls enrolled. Sixty percent of the children who were positive for *C. trachomatis* gave a clear, credible, detailed description of molestation.

In the setting of repeated abuse by a family member over a long period, the development of infection would be difficult to demonstrate. The 2010 CDC STD Treatment Guidelines do not recommend that samples for culture of *C. trachomatis* be obtained routinely from the pharynx and urethra in children who are suspected victims of sexual abuse.[26] The major reasons were the low yield from the urethra, the tendency for longer persistence of perinatally acquired pharyngeal infection, and the potential confusion with *C. pneumoniae*.[8]

Genital *Chlamydia trachomatis* Infections in Adolescents

As stated previously, *C. trachomatis* is the most prevalent STI and infectious disease in the United States. At least 70 percent (930,000) of cases were among men and women between 15 and 24 years of age, with the highest rates in women 15 to 19 years of age.[28,43] In sexually active adolescents, the prevalence commonly exceeds 10 percent and may exceed 20 percent.[43] The case rate of infection in females 15 to 19 years of age was 3378.2/100,000, more than 4 times the rate in males the same age (774.3/100,000).[28] The reasons for this sex discrepancy, which is seen in almost every age bracket, are not clear but may include better screening of female adolescents and increased susceptibility to infection in women. More than 70 percent of infections in women are asymptomatic. Reinfection is very common, with as many as 40 percent of adolescent women being reinfected, usually from an untreated partner, within 9 months.[7] Women sustain a disproportionate share of the morbidity from these *C. trachomatis* infections through their well-known complications of pelvic inflammatory disease, ectopic pregnancy, and tubal factor infertility.[26] Although *C. trachomatis* infection can be treated effectively with antibiotics, infections may result in tissue damage even with appropriate antimicrobial therapy. Although most infections are asymptomatic, in men they can cause urethritis and *C. trachomatis* infection is the most frequent cause of epididymitis in men younger than 30 years of age.[26] The symptoms of chlamydial genital tract infections are less acute than those of gonorrhea, consisting of a discharge that is usually mucoid rather than purulent.

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV) is an STD caused by the L1-3 serovars of *C. trachomatis* that are endemic in tropical and subtropical areas (e.g., parts of Southeast Asia, Africa, South America, India, and the Caribbean) but rare in the United States.[14,26] About 20 cases of LGV have been reported in children in the literature. Fewer than 1000 cases are reported in adults in the United States annually. Recently a resurgence of LGV infections has occurred among men who have sex with men (MSM) in Europe and the United States. Some common characteristics of these outbreaks are (1) it affected predominantly white MSM; (2) it presented mostly as proctocolitis (with no inguinal syndrome); (3) individuals affected had very high human immunodeficiency virus (HIV) coinfection rates (~70%); (4) patients often reported multiple sexual contacts met at casual sex gatherings: (5) 71 percent met partners at sex-on-premises venues or sex parties; and (6) 23 percent met partners via the Internet.[5]

LGV is a disease of the lymphatic tissue that has acute and chronic manifestations. Unlike other anogenital *C. trachomatis* infections, in which replication is confined to mucosal epithelial cells, LGV can replicate in macrophages and produce chronic invasive infection. Progression follows several defined stages, similar to syphilitic infection. The primary lesion of LGV is a small, inconspicuous, asymptomatic genital papule or ulcer that heals without a scar. Days to weeks later, unilateral acute lymphadenitis with bubo formation occurs at the site of lymphatic drainage of the primary lesion; acute hemorrhagic proctitis develops after a rectal lesion. Systemic symptoms can include fever, myalgia, or headache. Approximately one third of inguinal buboes become fluctuant and rupture; the remainder involute slowly. Although most patients recover from LGV after this secondary stage, a small number develop a chronic inflammatory response with fibrosis (as a result of the persistence of *Chlamydia* organisms in anogenital tissues) that can result in chronic genital ulcers or fistulas, rectal strictures, or genital elephantiasis. In females, the vulvar lymph drains to the retroperitoneal nodes; thus, they may not have inguinal lymphadenopathy but rather the genitoanorectal syndrome with rectovaginal fistulas and rectal strictures.

To our knowledge, cases in the pediatric population have not been reported since the emergence of the new clusters of cases in 2003. We reported a case of a 16-year-old boy with LGV proctocolitis after having receptive unprotected anal intercourse with a 30-year-old man he met on the Internet.[5] This history was obtained after the boy was found to be HIV positive. The diagnosis of LGV,

in particular when it presents with proctocolitis, relies on a high index of suspicion that would lead to emphasizing certain aspects of the history and ordering the pertinent diagnostic tests. Many pediatricians and pediatric gastroenterologists might not be familiar with the entity and might not entertain it as a diagnostic consideration in pediatric patients. The diagnosis can be further suggested by *C. trachomatis* testing—culturing the organism or, more commonly, by NAATs. Currently available NAATs will not differentiate LGV from other *C. trachomatis* serovars.[26] NAATs for *C. trachomatis* are also not FDA-cleared for testing rectal specimens. Trying to ascertain the *C. trachomatis* serovar for confirmation of LGV has therapeutic implications, because a single dose of azithromycin is unlikely to eradicate the infection and a 3-week course of doxycycline is the preferred treatment.[26]

Trachoma

Trachoma, the most important preventable cause of blindness in the world, is caused primarily by the A, B, Ba, and C serotypes of *C. trachomatis*.[15] It is endemic in the Middle East and Southeast Asia. The disease is spread from eye to eye via infected secretions. Flies are a frequent vector.

Trachoma begins as a follicular conjunctivitis, usually in early childhood. The follicles heal, leading to conjunctival scarring that may result in entropion, in which the eyelid turns inward so that the lashes abrade the cornea. It is the corneal ulceration secondary to the constant trauma that leads to scarring and blindness. Bacterial superinfection also may contribute to scarring. Blindness occurs years after the active disease.

Trachoma can be diagnosed clinically. The World Health Organization (WHO) suggests that at least 2/4 criteria must be present for a diagnosis of trachoma: (1) lymphoid follicles on the upper tarsal conjunctivae, (2) typical conjunctival scarring, (3) vascular pannus, and (4) limbal follicles.[15] The diagnosis is confirmed by culture, microscopy, or NAAT for *C. trachomatis* performed during the active stage of disease. Serologic tests are not helpful clinically because of the long duration of the disease and the high seroprevalence in endemic populations.

Poverty and lack of sanitation are important factors in the spread of trachoma. As socioeconomic conditions improve, the incidence of the disease decreases substantially. The WHO recommends single-dose azithromycin 20 mg/kg, maximum 1 g, for the treatment of trachoma in children. Numerous studies have demonstrated that mass community treatment with a single dose of azithromycin to all residents of a village dramatically reduced the prevalence and intensity of infection.[15] This effect continued for 2 years after treatment, probably by interrupting the transmission of ocular *C. trachomatis* infection.

Diagnosis of *Chlamydia trachomatis* Infections

Culture remains the gold standard of diagnosis for detection of *C. trachomatis* from the vagina or rectum in prepubertal children. *Chlamydia* culture has been defined further by the CDC as isolation of the organism in tissue culture and confirmation by microscopic identification of the characteristic inclusions by fluorescent antibody staining using a species-specific conjugated monoclonal antibody.[26]

The major advance in the diagnosis of *C. trachomatis* infection during the past decade has been the introduction of NAATs. These tests have high sensitivity, perhaps even detecting 10 to 20 percent more cases than is possible with culture, while retaining high specificity.[26] Currently, three commercially available NAATs are FDA approved and available in the United States: polymerase chain reaction (PCR), transcription-mediated amplification, and strand displacement amplification.[64,75] PCR and strand displacement amplification are DNA amplification tests; both use primers that target gene sequences on the cryptogenic *C. trachomatis* plasmid, which has approximately 10 copies per cell. Transcription-mediated amplification is an RNA amplification assay. NAATs that are currently commercially available have FDA approval for cervical and vaginal swabs from women, urethral swabs from men, and urine samples from men and women. Several studies have demonstrated that self-collected vaginal swabs also are suitable specimens.[26,64,75] *C. trachomatis* DNA and RNA may persist for 9 or more days after treatment.[47]

Even though culture is considered the gold standard for detection of *C. trachomatis* in children being evaluated for suspected sexual abuse, *C. trachomatis* culture is not standardized or regulated in any way. Sensitivity may vary significantly across laboratories. Enzyme immunoassays (EIAs) are not acceptable as confirmatory tests and have been associated with false positive results, especially when used with vaginal and rectal specimens.[65,69,130] The methods used for culture confirmation became an issue when several large commercial laboratories started using an EIA instead of fluorescent antibody staining and visual identification of inclusions for culture confirmation. This has resulted in at least one "outbreak" of *C. trachomatis* infection in the evaluation of suspected sexual abuse among residents and staff of an institution for those with intellectual disabilities in Ohio in 1990.[65,71] All of the "positive" cultures, mostly rectal specimens, were subsequently determined to be false-positives resulting from carryover of fecal material and bacteria in the culture specimens. The major advantage of culture is that it is 100 percent specific; however, because confirmation depends on visual identification of inclusions, a subjective component exists that could lead to misidentification of artifacts as chlamydial inclusions. This appears to have happened in two pseudo-outbreaks in other states, one in a residential institution[60] and one among children being evaluated for suspected sexual abuse.[144] In the latter, specimens for culture were outsourced to a commercial laboratory.

NAATs are not currently approved for the detection of *C. trachomatis* in rectogenital specimens or urine from prepubertal children and rectal specimens in adults.[26,64] Several studies, predominantly from MSM, found NAATs to be sensitive and specific for detection of rectal chlamydial infection. Data on the use of NAATs

for vaginal specimens or urine from children are very limited.[26,64,70] To date, four studies have been published comparing NAATs to *C. trachomatis* culture in children being evaluated for suspected sexual abuse.[16,51,52,91,109] They include the recent multicenter study by Black and colleagues[16,17] that evaluated SDA and TMA. Girardet and colleagues[51] and Kellogg and associates[91] primarily evaluated girls, most of whom were postpubertal. Both studies used ligase chain reaction, which is no longer manufactured. Kellogg and associates[91] also evaluated PCR in addition to LCR. These studies had major limitations—failure to use an independent reference standard in estimating test performance, failure to separately analyze test performance by age and gender, and the majority of girls were postpubertal and many were sexually active. The ages of the children ranged from 1 month to 17 years, with a mean age of 8.6 years, and 82.4 percent were female. Anatomic sites tested included vagina, cervix, rectum, pharynx, male urethra, and urine. The overall prevalence of *C. trachomatis* infection in these studies ranged from 6.6 to 8.3 percent by LCR and/or PCR and 0.8 to 5.3 percent by culture. Many discrepant results were found, especially between culture and NAATs, which were more frequent with rectal specimens, but the numbers of specimens from nongenital sites was too small to accurately assess the performance of the assays at these sites.

The recent CDC-sponsored multicenter study also evaluated the use of SDA and TMA using urine and genital swabs (vagina and urethra) in contrast to culture for diagnosis of *C. trachomatis* in children birth to 13 years of age.[17] Cultures for *C. trachomatis* were performed at the laboratories of each center, according to their own protocols. Culture protocols at all sites included the isolation of *C. trachomatis* in cycloheximide-pretreated McCoy cells, in shell vials or 24-well or 96-well tissue culture plates. The fixed monolayers were stained to detect chlamydial inclusions with fluorescein-conjugated *Chlamydia* genus–specific or *C. trachomatis* species–specific monoclonal antibodies. All samples were processed and tested according to manufacturers' protocols, except for the TMA tests, which were performed on previously frozen urine or swabs collected in BD ProbeTec sample collection medium. Test results that were positive by SDA for *C. trachomatis* were confirmed using in-house PCR targeting the *ompA* gene performed at the CDC. Of 485 female participants, 15 (3.1%) had a positive result for *C. trachomatis* by any test (1.4% by culture; 2.3% by vaginal NAAT; 2.7% by urine NAAT). All participants who had a positive vaginal culture for *C. trachomatis* also had positive urine NAAT. Two girls had positive *C. trachomatis* cultures from rectal swab specimens, but negative vaginal swab specimens by both culture and NAATs and negative urine NAATs. No discrepant results were found in any of the participants tested by SDA and TMA for *C. trachomatis*. All *C. trachomatis*–positive results were confirmed by DNA sequence genotyping. The sensitivity of vaginal culture for *C. trachomatis* was 39 percent in all girls studied. In contrast, the sensitivities of urine and vaginal swab NAATs were 100 and 85 percent in all female children, respectively, for detection of *C. trachomatis*. Based on the results of this study, the 2010 CDC STD Treatment Guidelines now recommend that NAATs can be used for detection of *C. trachomatis* in girls being evaluated for suspected sexual abuse, with important limitations, as follows[26]:

1. Because the prevalence of *C. trachomatis* in this population is low, additional testing is probably necessary.
2. Extrapolation cannot be made from these results to other NAATs, specifically PCR, or used in specimens other than vagina and urine in girls.
3. Recommendations cannot be made on the use of these assays in prepubertal boys.

Some of the more recently available commercial NAATs, such as TMA (Aptima 2), offer an alternative target confirmation method that can be used on the same testing platform; however, no data exist on the use of this confirmatory test in this setting. Additional options include sending blinded specimens to an independent or reference laboratory for confirmation testing, confirming a NAAT-positive result by culture test (requires a separate, invasive specimen), or use of a second, alternative technology commercial NAAT. Specimens collected from children for forensic applications should be retained in the laboratory for purposes of additional testing, in accordance with local policies and procedures. A new generation of NAATs, including highly sensitive point-of-care tests, will be coming to market.[64,82] These assays will need to be evaluated in children, because extrapolation cannot be made from their performance in adults or adolescents.

Treatment

Chlamydial infections in older children may be treated with oral erythromycin 50 mg/kg/day orally four times daily, with a maximum of 2 g/day for 7 to 14 days.[26] Children older than 8 years of age may be treated with tetracycline 25 to 50 mg/kg/day orally four times daily for 7 days. Azithromycin 1 g orally as a single dose also may be used in children who weigh at least 45 kg, are 8 years of age or older, or both.[26]

The first-line treatment regimen recommended by the CDC for uncomplicated *C. trachomatis* genital infection in men and nonpregnant women is azithromycin 1 g orally as a single dose or doxycycline 100 mg orally twice daily for 7 days. Alternative regimens are erythromycin base 500 mg orally four times daily for 7 days, erythromycin ethylsuccinate 800 mg orally four times daily for 7 days), levofloxacin 500 mg orally once daily for 7 days. The high erythromycin dosages may not be well tolerated. Doxycycline and ofloxacin or levofloxacin are contraindicated in pregnant women; quinolones are contraindicated in persons younger than 18 years of age. However, use of levofloxacin offers no advantages over doxycycline. For pregnant women, the recommended treatment regimen is also single-dose azithromycin. Alternative regimens are erythromycin base 500 mg orally twice daily for 7 days, amoxicillin 500 mg orally three times daily for 7 days, erythromycin base 250 mg orally four times daily for 14 days, and erythromycin ethylsuccinate 800 mg orally four times daily for 7 days

or 400 mg orally four times daily for 14 days. Amoxicillin at this dosage is as effective as azithromycin or any of the erythromycin regimens and is much better tolerated.

INFECTION CAUSED BY *CHLAMYDIA PSITTACI*

Human infection with *C. psittaci* was described first probably by Juergensen in 1874 or Ritter in 1876. Ritter described seven cases of an unusual pneumonia that appeared to be caused by parrots and finches that were caged in the study of his brother's home in Switzerland. After these reports, several outbreaks of a similar disease in Europe established the association with exposure to birds. The term *psittacosis* was coined by Morange in 1892 from the Greek word for parrots, *psittakos*.

The Organism

C. psittaci is a diverse species that affects psittacine and nonpsittacine birds.[1] The known host range includes 259 avian species.[25,28,79,126] Birds that have been reported to have *C. psittaci* infection contain six major domestic species: chickens, turkeys, Pekin ducks, Muscovy ducks, geese, and pigeons. Infections in these species have been associated with significant outbreaks in humans.[24,28,146] In the past, chlamydial infection in psittacine birds was termed *psittacosis*, whereas disease in wild and domestic fowl was called *ornithosis*. However, because *C. psittaci* strains isolated from psittacine or nonpsittacine species have been shown to produce identical disease in birds of either grouping, this distinction is artificial. The more universally applicable term *chlamydiosis* can be usefully employed to describe chlamydial infections of all animal species.

Epidemiology

Chlamydial infections in birds are important because they represent a biologic hazard to human health and economic loss to the poultry industry.[25,28,146] *C. psittaci* has been recovered from symptomatic and apparently healthy birds. Infection principally involves the gastrointestinal tract, and the chlamydiae are shed in feces or through infectious respiratory tract discharges.[154] Clinically inapparent, latent infections may be the predominant state. Overt clinical disease may be activated by stress factors, including overcrowding, poor nutrition, other bacterial and viral infections, and transportation.

Apparently healthy birds shedding chlamydiae can infect other birds or humans through contact. Infectious chlamydiae in respiratory secretions or feces may remain viable for several months. Transmission of disease is mainly through aerosols of fecal or feather dust, but oral infection is an alternative route. Transmission through eggs has been shown in chickens, ducks, seagulls, and psittacine birds.[154] However, most infected eggs do not hatch. In the nest, parent birds may infect their young, which may carry the infectious agent for many years. Young birds are more susceptible to infection than are older birds, and some species seem to be more susceptible than others. Often, disease carriers may be identified by the transmission of disease to other susceptible birds or by the sudden death of young nestlings with apparently healthy parents.[137]

From 2003 through 2010, 94 human cases of psittacosis were reported to the CDC, a dramatic decrease from 935 cases reported from 1998 to 2003.[28] Eighty-five percent of cases of psittacosis in the United States were associated with exposure to birds; 70 percent of these reported cases were the result of exposure to caged pet birds.[146] Individuals at highest risk for acquiring psittacosis included bird owners or fanciers and pet shop employees. Since 1984, several major outbreaks of psittacosis have occurred in the United States in turkey-processing plants, in which approximately 300 persons were infected. Workers exposed to turkey viscera were at the highest risk for acquiring infection.[25,79] In 1995, the CDC investigated an outbreak of avian chlamydiosis in a shipment of more than 700 pet birds from a Florida bird distributor to the Atlanta area.[119] Affected birds included parrots, parakeets, finches, lovebirds, cockatiels, conures, and canaries. Clinical psittacosis or serologic evidence of *C. psittaci* infection was found in 30.7 percent of households with birds from the infected flock. An average of 21 days (range, 1 to 47 days) elapsed between purchase of the bird and the onset of symptoms. Most of the infected individuals had mild or asymptomatic illnesses. Among persons in exposed households, illness occurred more frequently if the recently purchased bird had become sick or had died. Kissing or nuzzling, handling, and feeding the bird all were significantly associated with the development of clinical psittacosis, but in contrast to earlier studies, cleaning the bird's cage was not. The risk for acquiring clinical psittacosis varied significantly by type of bird to which the individual was exposed. The attack rate was highest for individuals exposed to parrots.

Inhalation of infectious aerosols derived from the feces, fecal dust, or secretions of *C. psittaci*–infected animals is thought to be the primary route of infection. The source birds can be infected asymptomatically or can show signs of infection, such as anorexia, ruffled feathers, depression, and watery green droppings. Psittacosis frequently is a systemic infection in birds, and the turkey strains can induce severe pericarditis.[154]

Psittacosis is an uncommon occurrence in children. In a series of 135 cases from Australia observed during a 15-year period, the youngest patient was 17 years of age.[162] Children may be less likely to be exposed to birds. Bird-keeping is more commonly a hobby of adults, and the parents are the ones who usually clean the cage of the family's pet bird. An outbreak of psittacosis involving two adolescents was reported from a small village in Scotland. The source of the infection appeared to be the local pet shop, which had taken delivery of four lovebirds, two of which died shortly after arrival.[120]

Clinical Manifestations

Infection with *C. psittaci* in humans may range from clinically inapparent to severe infection involving multiple

organ systems, as well as pneumonia.[9,45,119,162] Symptomatic *C. psittaci* infection in humans may present as two forms: a severe atypical pneumonia or pneumonitis and a systemic toxic or septic form without respiratory involvement. In both cases, fever, chills, muscle aches and pains, and severe headache are typical. Other manifestations may be diarrhea, nausea, and vomiting. The mean incubation period is 15 days after exposure (range, 5 to 21 days). The onset usually is abrupt, with complaints of fever, cough, and headache. The fever is high and frequently associated with rigors and sweats. The headache can be so severe that meningitis can be considered a possibility; 33 percent of patients in the Australian series underwent lumbar puncture.[162] The cough usually is nonproductive, and rales may be heard on auscultation. Chest radiographs generally are abnormal, with variable infiltrates. Pleural effusions also may be present. In contrast, most of the individuals in the Atlanta outbreak had very mild disease characterized by fever, headache, and cough.[119]

Laboratory Findings

The white blood cell count usually is not elevated, but mild leukocytosis may be present. Almost 50 percent of patients in the Australian series had abnormal liver function test results, including elevated levels of aspartate aminotransferase, alkaline phosphatase, and bilirubin.[162]

Diagnosis

The CDC and the Council of State and Territorial Epidemiologists have established national case definitions for epidemiologic surveillance of psittacosis. The updated case definitions were published in 2010.[146] A patient is considered to have a confirmed case of psittacosis if clinical illness is compatible with psittacosis and the case is laboratory confirmed by one of two methods: isolation of *C. psittaci* from respiratory specimens (e.g., sputum, pleural fluid, or tissue) or blood or fourfold or greater increase in antibody (immunoglobulin [Ig]G) against *C. psittaci* by complement fixation or microimmunofluorescence (MIF) between paired acute- and convalescent-phase serum specimens obtained at least 2 to 4 weeks apart. A patient is considered to have a probable case of psittacosis if the clinical illness is compatible with psittacosis and one of the two following laboratory results is present: supportive serology (e.g., *C. psittaci* antibody titer [IgM] of 32 or greater in at least one serum specimen obtained after onset of symptoms) or detection of *C. psittaci* DNA in a respiratory specimen (e.g., sputum, pleural fluid, or tissue) via amplification of a specific target by PCR assay.

Most diagnoses are established by clinical presentation and positive antibodies against *C. psittaci* in paired sera using MIF methods. The MIF is more sensitive and specific than the previously used complement fixation tests; however, some cross reactivity occurs with other chlamydiae (i.e., *C. pneumoniae*, *C. trachomatis*, and *C. felis)*, so a titer result less than 1:128 should be interpreted with caution.[155] Acute-phase serum specimens should be obtained as soon as possible after the onset of symptoms, and convalescent-phase serum specimens should be obtained at least 2 weeks after the first specimen. Because antimicrobial treatment can delay or diminish the antibody response, a third serum sample 4 to 6 weeks after the acute sample might help confirm the diagnosis. To increase the reliability of serologic results, acute and convalescent sera should be analyzed simultaneously at the same laboratory.

C. psittaci also can be isolated from the patient's sputum, pleural fluid, or clotted blood during acute illness and before treatment with antimicrobial agents. Although *C. psittaci* will grow in the same culture systems used for the isolation of *C. trachomatis* and *C. pneumoniae*, very few laboratories culture for *C. psittaci*, mainly because of the potential biohazard.

Real-time PCR (rt-PCR) assays have been developed for use in the detection of *C. psittaci* in respiratory specimens.[9,112] These assays can distinguish *C. psittaci* from other chlamydial species and identify different *C. psittaci* genotypes. While the assays appear to be highly sensitive and specific in avian samples, they have not yet been validated for use in human samples. Because proper sample collection techniques and handling are critical to obtain accurate test results, clinical laboratories performing these tests should be contacted directly for specifics on specimen submission.

Information about laboratory testing is available from state public health departments. Few commercial laboratories provide MIF testing, and manufacturing problems in 2009 resulted in limited availability of the MIF testing kits. Certain laboratories accept human specimens to confirm *C. psittaci* infection through culture, MIF, or PCR (Table 193-2).

Treatment

The recommended treatment of psittacosis in adults and children older than 8 years of age is tetracycline 500 mg orally four times daily for 7 to 10 days.[148] Erythromycin 50 mg/kg/day, up to 2 g/day, for 7 to 10 days also can be used. The experience in the Australian series[162] and anecdotal reports suggest that tetracycline may be more effective than erythromycin. The initial infection does not appear to be followed by long-term immunity. Reinfection and clinical disease can develop within 2 months of treatment; two well-documented cases of reinfection are reported in the literature. A pet shop employee had two episodes of psittacosis 11 months apart. Each episode met the CDC's confirmed case definition.[24]

INFECTION CAUSED BY *CHLAMYDIA PNEUMONIAE*

The Organism

The first isolates of *C. pneumoniae* were obtained serendipitously during trachoma studies in the 1960s.[55] After the recovery of a similar isolate from the respiratory tract of a college[57,149] applied the designation TWAR after

their first two isolates, TW-183 and AR-39. On the basis of inclusion morphology and staining characteristics in cell culture, *C. pneumoniae* initially was considered a *C. psittaci* strain. Subsequent analysis, however, has demonstrated that this organism is distinct from both *C. psittaci* and *C. trachomatis.*[22,56] Sequencing has revealed that *C. pneumoniae* differs significantly from *C. trachomatis* in several areas. *C. pneumoniae* encodes 21 polymorphic membrane proteins versus 9 in *C. trachomatis*. Polymorphic membrane proteins may be surface exposed in *C. pneumoniae.*[88,136] Ultrastructural studies have demonstrated an elementary body morphology distinct from that of *C. trachomatis* and *C. psittaci* (Fig. 193-2).[30] However, some isolates of *C. pneumoniae*, including IOL-207, have been found to have round elementary bodies.[23,127,129] Thus, it may not be a consistent species characteristic. At this point, a strain typing system for *C. pneumoniae* has not been developed. A plasmid has been detected in a single isolate obtained from a horse but not from any human isolate of *C. pneumoniae*.

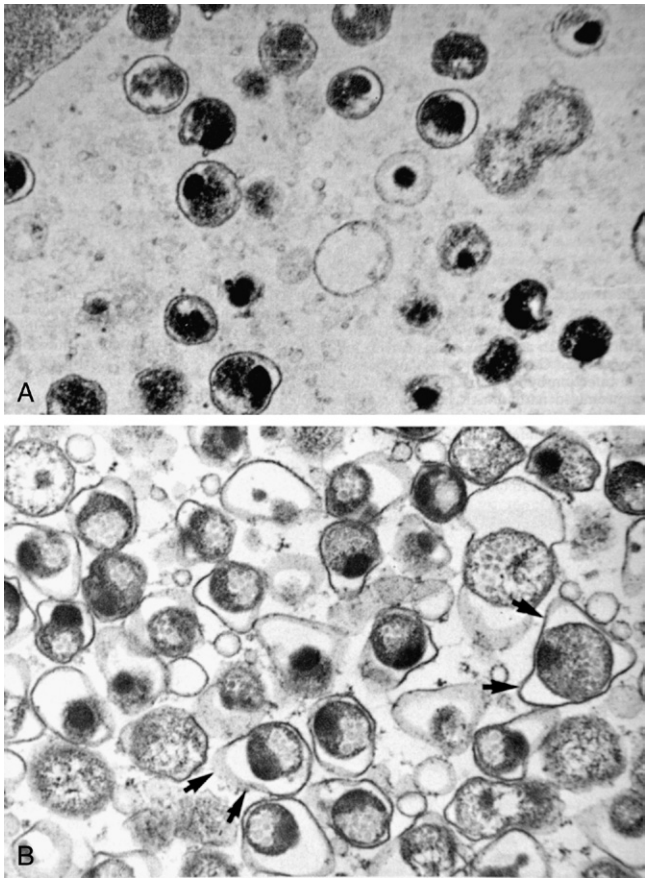

FIGURE 193-2 ■ Electron micrograph of *Chlamydia trachomatis* **(A)** and *Chlamydia pneumoniae* **(B)** inclusions demonstrating the morphology of the elementary body. The elementary bodies of *C. pneumoniae* have a pear shape because of a loose periplasmic membrane *(arrow),* unlike the typically round elementary bodies of *C. trachomatis* and *C. psittaci.*

Epidemiology

C. pneumoniae appears to be a common human respiratory pathogen. The organism also has been isolated from nonhuman mammalian species, including a horse, koalas, bandicoots, and reptiles and amphibians, although the role these infections may play in human disease is unknown.[20,40,86,88,98,117,131] The animal isolates are diverse and have DNA sequences that differ slightly from human *C. pneumoniae* isolates.[115] It has been hypothesized that human *C. pneumoniae* may be zoonotic in origin.[115,117,121,123] Human isolates have been found to be relatively uniform.[17] Currently no strain typing system has been developed for *C. pneumoniae.* The mode of transmission remains unclear but probably involves infected respiratory tract secretions. Acquisition of infection by droplet aerosol was described during a laboratory accident.[81] *C. pneumoniae* can remain viable on Formica countertops for 30 hours and can survive small-particle aerosolization.[41,146] Spread of *C. pneumoniae* within families and enclosed populations such as military recruits has been described.[92,94,158] The proportion of community-acquired pneumonia associated with *C. pneumoniae* infection has ranged from 0 to 19 percent, varying with the geographic location, the age group examined, and the diagnostic methods used.*

Studies of the role of *C. pneumoniae* in lower respiratory tract infections in pediatric populations have found evidence of infection in 0.3 to more than 44 percent

(Table 193-3). Most of these studies relied entirely on serology for diagnosis. Early studies that relied on serology suggested that infection in children younger than 5 years of age was rare[100,157]; however, in a study of Filipino children younger than 5 years with lower respiratory tract infection, nearly 10 percent had either acute or chronic antibody to *C. pneumoniae*.[137] In Brooklyn, the proportion of lower respiratory tract infections associated with *C. pneumoniae*, as determined by culture, increased from 9 percent in children younger than 5 years to 19 percent in children and adolescents 5 to 16 years of age.[31]

Studies that have used culture or PCR have found a poor correlation with serology, especially in children.* Although 7 to 13 percent of children 6 months to 16 years of age enrolled in two multicenter pneumonia treatment studies were culture positive and 7 to 18 percent met the serologic criteria for acute infection with the MIF test, they were not the same patients.[19,75] Only 1 to 3 percent of the culture-positive children met the serologic criteria, and approximately 70 percent were seronegative.

In studies to date, acute infection with *C. pneumoniae* does not appear to vary by season. Recent studies have found much lower prevalence of infection than reported in the 1990s, suggesting that cycling over the course of time may occur.[76,84,96,100,104,106]

Prolonged culture positivity lasting several weeks to several years after acute infection has been reported.[31,38,72] Asymptomatic nasopharyngeal carriage also occurs in 2 to 5 percent of adults and children.[18,38,53,82,83,96] The role that asymptomatic carriage plays in the epidemiology of *C. pneumoniae* is not known, but possibly these persons could serve as a reservoir for spread of infection.

Clinical Manifestations

Most *C. pneumoniae* respiratory infections are mild or asymptomatic. Longitudinal serologic data obtained during an epidemic among military recruits in Finland suggest that only approximately 10 percent of infections result in clinically apparent pneumonia.[92,94] Initial reports emphasized mild atypical pneumonia clinically resembling that associated with *Mycoplasma pneumoniae*.[54,55,138,140] In several subsequent studies, however, pneumonia associated with *C. pneumoniae* was clinically indistinguishable from other pneumonias.[19,75,77] Coinfection with other pathogens, especially *M. pneumoniae*, *Streptococcus pneumoniae*, and viruses are frequent.[19,75,77,147,149] In one multicenter pneumonia treatment study, 20 percent of the children with positive *C. pneumoniae* cultures were coinfected with *M. pneumoniae;* they could not be distinguished from children who were infected with either organism alone.[19] *C. pneumoniae* has been associated with severe illness and even death, although the role of preexisting chronic conditions as contributing factors in many of these patients is difficult to assess. In some cases, however, *C. pneumoniae* clearly appears to be implicated as a serious pathogen, even in the absence of underlying disease. *C. pneumoniae* was isolated from the respiratory tract and the pleural fluid of a previously healthy adolescent boy with severe pneumonia complicated by respiratory tract failure and pleural effusions (Fig. 193-3).[4]

C. pneumoniae appeared to be responsible for 14 to 19 percent of episodes of acute chest syndrome in children with sickle-cell disease.[35,99,113,114] *C. pneumoniae* infection in these patients appeared to be associated with more severe hypoxia than was infection with *M. pneumoniae*.

C. pneumoniae may act as an inflammatory trigger for asthma. Several cases of culture-documented *C. pneumoniae* infection in patients with significant bronchospasm have been reported.[61,72] Asthmatic bronchitis was diagnosed in one patient, and she was receiving systemic and inhaled steroids.[72] This patient did not improve until her chlamydial infection was treated. Hahn and associates[61] reported an association between serologic evidence of acute *C. pneumoniae* infection and wheezing in adults

*References 19, 38, 48, 49, 75, 99, 101.

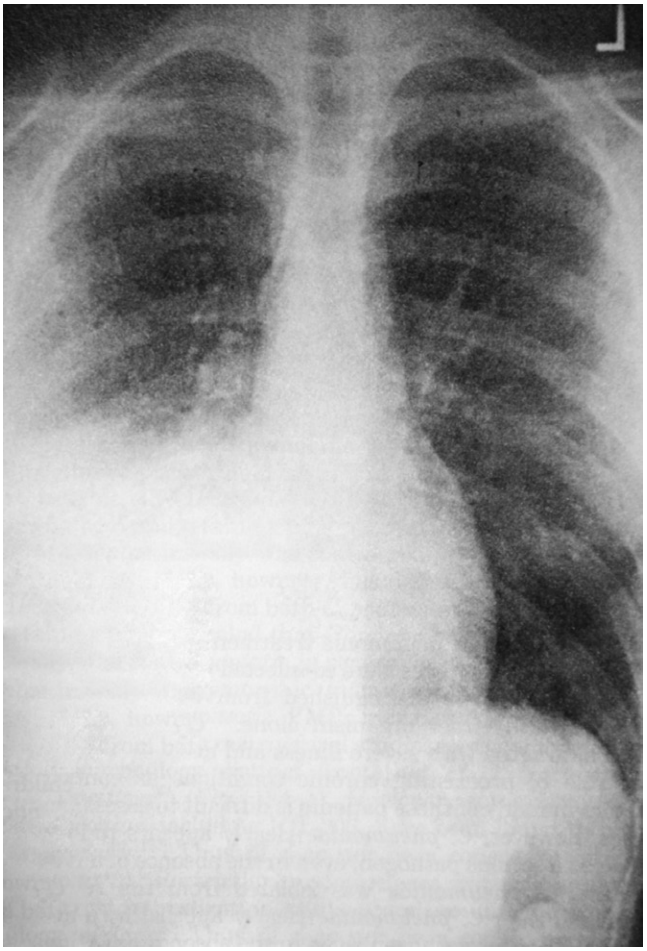

FIGURE 193-3 ■ Chest radiograph of a 19-year-old man with *Chlamydia pneumoniae* pneumonia demonstrating pleural effusion in the right lung. *C. pneumoniae* was isolated from the pleural fluid.

seen for lower respiratory tract illness. However, they were able to isolate the organism from only 1/365 patients. As part of a study in children, *C. pneumoniae* was isolated from 13/118 children (11%) 5 to 15 years of age who were evaluated initially for either new or acute exacerbations of asthma.[38] Treatment of the infection appeared to result in both clinical improvement and improvement in pulmonary function test scores. Only 5 of the children with confirmed infection had detectable IgG antibody to *C. pneumoniae*. One child who did not comply with his antibiotic therapy was culture positive on five occasions during a 3-month period. Anti–*C. pneumoniae* antibody as determined by MIF was never detected. Specific anti–*C. pneumoniae* IgE was, however, detected in 85.7 percent of the culture-positive asthmatics in contrast to 9 percent of the children with *C. pneumoniae* pneumonia who were not wheezing.[39] This finding suggests that the bronchial reactivity seen with *C. pneumoniae* infection may be IgE mediated. The potential prolonged, persistent *C. pneumoniae* infection may produce chronic inflammation and trigger bronchospasm in susceptible persons. *C. pneumoniae* has been demonstrated to induce in vitro ciliostasis in ciliated bronchial epithelial cells.[141,143] Animal studies also suggest that steroids can reactivate *C. pneumoniae* lung infection in mice.[106] In addition, immune-mediated phenomena, including erythema nodosum and iritis, have been described as complicating *C. pneumoniae* infection.[145,147,155,157]

The role of *C. pneumoniae* in upper respiratory tract infections is not as well defined. *C. pneumoniae* has been isolated from the middle ear fluid of children and adults with otitis media.[18,123-125] Block and colleagues[18] recovered *C. pneumoniae* from the middle ear fluid of eight children, 3 months to 14 years of age, with acute otitis media. *C. pneumoniae* was the sole pathogen isolated in two patients. Co-pathogens in the remaining six patients included β-lactamase–positive *Haemophilus influenzae* and *Moraxella catarrhalis*, along with penicillin-resistant and penicillin-sensitive *S. pneumoniae*. Five of the children who were positive for *C. pneumoniae* responded favorably despite not being treated with antibiotics active against the organism, either a course of an oral β-lactam or single-dose intramuscular ceftriaxone. Symptoms suggestive of sinus involvement are not uncommon in patients with upper respiratory tract infection associated with *C. pneumoniae*, but only one case of isolation of the organism, from a 47-year-old man with sinusitis, has been reported.[77,78] Cultrara and colleagues[34] examined nasopharyngeal swabs, ethmoid and maxillary sinus biopsy samples, and adenoids from 20 children, 3 to 16 years of age, with chronic sinusitis. *C. pneumoniae* was not isolated from any sinus tissue but was isolated from the nasopharyngeal swab and adenoid tissue of a 6-year-old child. The results of this study suggest that *C. pneumoniae* does not play a significant role in chronic sinusitis in children.

Diagnosis

A specific laboratory diagnosis of *C. pneumoniae* infection can be made by isolation of the organism from nasopharyngeal or throat swabs, sputum, or pleural fluid, if present. The nasopharynx appears to be the optimal site for isolation of the organism.[19] *C. pneumoniae* grows readily in cell lines derived from respiratory tract tissue, specifically, HEp-2 and HL cells.[132,135] Culture with an initial inoculation and one passage can take 4 to 7 days.

Nasopharyngeal cultures can be obtained with Dacron-tipped, wire-shafted swabs. Each lot of swabs should be treated in a mock infection system to ensure that no inhibitory effects occur on either the viability of cells or recovery of chlamydiae. Specimens for culture should be placed in appropriate transport media, usually a sucrose phosphate buffer with antibiotics and fetal calf serum, and stored immediately at 4°C (39.2°F) for no longer than 24 hours. Viability decreases if specimens are held at room temperature. If the specimen cannot be processed within 24 hours, it should be frozen at –70°C (–94°F) until culture can be performed. After 72 hours of incubation, culture confirmation can be performed by staining with either a *C. pneumoniae* species–specific

or a *Chlamydia* genus–specific (anti-LPS) fluorescein-conjugated monoclonal antibody.[116-118,132,135] Unfortunately, no commercially produced *C. pneumoniae*–specific culture-confirmation reagents are available. If a genus-specific antibody is used, *C. pneumoniae* should be confirmed by differential staining with a specific *C. trachomatis* antibody; if that result is negative, the isolate is either *C. pneumoniae* or *C. psittaci*. If the patient has not had avian exposure, psittacosis would be highly unlikely.

The most common method still used by investigators for the diagnosis of *C. pneumoniae* infection is serologic testing. Assays available for detection of *C. pneumoniae*–specific antibodies include MIF tests, enzyme-linked immunosorbent assays (ELISAs), and EIAs, each of which exists in a variety of in-house and commercial versions.[151] MIF is considered by the CDC to be the only currently acceptable serologic test, and, therefore, it is considered to be the reference standard for serodiagnosis, despite significant limitations.[36] The recommendations proposed by the CDC[36] in 2001 defined the criteria for serologic diagnosis of acute *C. pneumoniae* infection as a single IgM titer of 1:16 or greater or a fourfold increase in the IgG titer, as determined by MIF testing. The use of single IgG titers was discouraged. However, not only is the literature replete with studies that deviate widely from the proposed guidelines[100] but also several limitations exist that are inherent for serodiagnosis of *C. pneumoniae* infection, even when these guidelines are observed. The MIF assay has been repeatedly and conclusively demonstrated to be insensitive and have poor correlation with the detection of the organism by culture or PCR assay, particularly for children.[49,100] Seventy percent of children 6 months to 16 years of age in two multicenter pneumonia treatment studies and 7/12 (58.3%) children 5 to 16 years of age with acute wheezing and who had culture-documented infection had seronegative results by MIF test.[19,38,75,76] Only 1 to 3 percent of culture-positive children in the former study and 25 percent in the latter met the serologic criteria for acute infection. The majority of the children remained seronegative, even after 3 months of follow-up.[38]

Background rates of seropositivity also can be high in some populations. Hyman and associates,[82,84] as part of a study of asymptomatic *C. pneumoniae* infection in subjectively healthy adults in Brooklyn, found 81 percent to have IgG or IgM titers of 16 or higher. Seventeen percent had evidence of "acute infection" (i.e., IgG titer ≥512, IgM titer ≥16, or both). However, none of these persons were culture or PCR positive. Similar results were reported by Kern and associates[93] in healthy firefighters and policemen in Rhode Island. Some IgG antibody may result from a heterotypic response to other chlamydial species because cross reactions with MOMP occur among the three species, as do cross reactions caused by the genus LPS antigen. Moss and colleagues[121] reported that antibodies to *C. pneumoniae* and *C. psittaci* were found in as many as half of all chlamydial IgG–positive persons attending an STD clinic. This point is reinforced by the observation that studies from the early 1980s suggesting *C. trachomatis* as a cause of community-acquired pneumonia and pharyngitis in adults and children were probably detecting antibody to *C. pneumoniae* rather than *C. trachomatis*[50,94,95,97,128] or, in one outbreak in a boys school, *C. psittaci*.[126] Other organisms that have been reported as possibly causing cross-reactions on MIF are *Bartonella*[108,110] and *Bordetella pertussis*.[85,87] The latter could be significant because older children and adolescents with pertussis frequently have a chronic cough or severe bronchitis, which is a clinical feature often ascribed to *C. pneumoniae*. Other studies have found significant homology between human and *C. pneumoniae* heat shock protein 60 (HSP-60) and *Escherichia coli* GroEL.[122,124]

Moreover, the MIF test is not standardized, and reading of the slides has a large subjective component and requires an experienced microscopist. Littman and associates[105] evaluated the interlaboratory reliability of the MIF test for measurement of *C. pneumoniae*–specific IgA and IgG titers for 392 serum samples, using reagents and antigens obtained from a common source. The investigators reported the exact agreement of IgA and IgG titers to be 55 and 38 percent, respectively, and the agreement within a twofold dilution to be 75 and 66 percent, respectively. EIAs may overcome some of the limitations of the MIF test by being objective and less technically complex. However, the CDC did not endorse any EIA, pending demonstration of adequate sensitivity and specificity in contrast to the MIF test. None of the currently available EIAs have FDA approval. Hermann and colleagues[80] compared seven commercial EIAs or ELISAs (one of which was genus-specific) with four MIF assays for detection of specific IgG antibodies, using serum samples from 80 healthy subjects; they reported sensitivities and specificities ranging from 88 to 100 and 42 to 100 percent, respectively. Similar results have been reported by others with the same assays in different populations, including children.[99,107,125,150,151,153]

The number of *C. pneumoniae* organisms present in the respiratory tract of persons with pneumonia or other respiratory tract diseases is smaller than the number found in genital *C. trachomatis* infection. PCR appears to be the most promising technology in the development of a rapid, nonculture method for detection of *C. pneumoniae*. More than 25 in-house PCR assays for detection of *C. pneumoniae* in clinical specimens have been reported in the literature.[100,107] None of these assays is standardized or extensively validated in contrast to culture for detection of *C. pneumoniae* in respiratory specimens. None is commercially available or has FDA approval. Major variations in these methods include collection and processing of specimens, primer design, nucleic acid extraction, detection and identification of amplification products, and ways to prevent possible false-positive and inhibitory reactions. The primers used most frequently have been those based on the *omp1* gene, the 16S rRNA gene, the 16S and 16S-23S spacer rRNA genes, and a *C. pneumoniae*–specific cloned *Pst*I fragment.[99,100] Some assays have used single amplification, and some have been nested. Methods for detecting the amplification product include agarose gel electrophoresis, Southern blot, EIA, and polyacrylamide gel electrophoresis.[100] Studies suggest significant interlaboratory variation in performance of PCR for *C. pneumoniae*.[2,21,104] Use of nested PCRs has been associated with a high risk for contamination because of amplicon

carryover.[2] Real-time PCR appears to be the method of choice, preferably using MOMP-based primers; several assays have been reported in the literature, but none has been extensively validated in contrast to culture.[2,3,101]

Treatment

Chlamydia spp. are susceptible to tetracyclines, macrolides, and quinolones.[63,66] *C. pneumoniae*, like *C. psittaci*, is resistant to sulfonamides.[63,66] To date, few published data have described the response of *C. pneumoniae* to antimicrobial therapy. Most of the treatment studies of pneumonia caused by *C. pneumoniae* published thus far have relied entirely on diagnosis by serology; consequently, microbiologic efficacy could not be assessed. Anecdotal reports have suggested that prolonged courses, up to 3 weeks, of either tetracyclines or erythromycin may be needed to eradicate *C. pneumoniae* from the nasopharynx of adults with influenza-like illness and pharyngitis.[72] The results of two pediatric multicenter pneumonia treatment studies found that 10-day courses of erythromycin and clarithromycin and 5 days of azithromycin suspension were equally efficacious; they eradicated the organism in 79 to 86 percent of children.[19,75,77,133] Quinolones, including levofloxacin and moxifloxacin, also have been demonstrated to have 70 to 80 percent efficacy in eradicating *C. pneumoniae* from adults with community-acquired pneumonia.[67-69] Most patients improved clinically despite persistence of the organism. Persistence does not appear to be secondary to the development of antibiotic resistance, because the MICs of the isolates obtained after treatment did not change.[63,66-69,76,133,134]

On the basis of these limited data, the following regimens for respiratory tract infection caused by *C. pneumoniae* can be suggested: in adults, doxycycline 100 mg twice daily for 14 to 21 days; tetracycline 250 mg four times daily for 14 to 21 days; azithromycin 1.5 g for 5 days; levofloxacin 500 mg/day orally or intravenously for 7 to 14 days; and moxifloxacin 400 mg/day orally for 10 days. For children, suggested regimens include erythromycin suspension 50 mg/kg/day for 10 to 14 days; clarithromycin suspension 15 mg/kg/day for 10 days; and azithromycin suspension 10 mg/kg on day 1 followed by 5 mg/kg/day once daily on days 2 to 5. Some patients may require retreatment.

SECTION **XIX**

RICKETTSIAL DISEASES

CHAPTER 194

Rickettsial and Ehrlichial Diseases

Paul M. Lantos • Ross McKinney Jr.

The Rickettsiaceae are a family of organisms that share a fascinating history and common biology. The critical steps in the epidemiology were first characterized by Howard T. Ricketts in the early 20th century. He was doing field work in the Bitterroot Valley in Montana and described that Rocky Mountain spotted fever (RMSF) was transmitted by the Rocky Mountain wood tick. Interestingly, before he did his work demonstrating tick-dependent transmission using guinea pigs, the fact that human transmission was through a tick vector had already been proved. In the *Transactions of the Chicago Pathological Society*, Dr. Ricketts reported:

> At the time this work was done I had no knowledge of previous experiments which demonstrated the ability of the "wood tick" to transfer spotted fever. Recently I have had authoritative information that Dr. L. P. McCalla and Dr. H. A. Brereton, of Boise City, Idaho, transmitted the disease from man to man in two experiments. The tick was obtained "from the chest of a man very ill with spotted fever," and "applied to the arm of a man who had been in the hospital for two months and a half, and had lost both feet from gangrene due to freezing." On the eighth day the patient became ill and passed through a mild course of spotted fever, leaving a characteristic eruption. The experiment was repeated by placing the tick on a woman's leg, and she likewise was infected with spotted fever. Although these results received no publicity other than that given in reports to local societies, I take pleasure in according to Dr. McCalla and to his colleague, Dr. Brereton, the credit of having first shown that the tick may act as a carrier of spotted fever. Their experiments preceded by more than a year those of Dr. King and of myself, and they were performed with the full consent of the patients concerned.[148]

The study was more fully described by Dr. McCalla in 1908.[115]

Sadly, funding for Dr. Ricketts' RMSF research dried up, and he moved to Mexico to investigate an outbreak of tabardillo, a Mexican typhus fever, which he suspected was similar in biology to RMSF. He identified lice as the vector for the disease, but in his attempt to isolate the causative organism, he contracted typhus and died. Shortly before his death, he learned that the state of Montana was ready to resume funding of his research on RMSF. (This is, of course, a cautionary tale to all academics with insecure funding.)

Rickettsiae are small coccobacilli in the class Alphaproteobacteria,[69] visible by light microscopy, that cause their disease intracellularly. The challenging nature of their physical identification was borne out by the fact that Howard Ricketts thought the cause of RMSF was a viral infection. The organism eventually named *Rickettsia rickettsii* was first described by Simeon Burt Wohlbach in 1916, although it took several years for his identification of a 0.2- to 0.5-μm gram-negative organism to be confirmed.[76,193] Rickettsiae cause disease by multiplying in the vascular endothelium, producing a generalized vasculitis involving mostly small blood vessels and symptoms that can involve nearly the entire body.

The human rickettsiae are in the family Rickettsiaceae, which is divided into two genera, *Rickettsia* and *Orientia*.[35] The rickettsiae are the more important pathogens and consist of the spotted fever group and the typhus group.[165] *Orientia* includes only one pathogen, *Orientia tsutsugamushi*, the cause of scrub typhus. The Anaplasmataceae family is closely related and is divided into two genera, *Anaplasma* and *Ehrlichia*.[145]

All of the infections discussed in this chapter are transmitted by arthropod vectors. The spotted fever group of rickettsiae is predominantly transmitted by ticks, although rickettsialpox is spread by mites. Scrub typhus is spread by human body lice as well as by ticks, and murine typhus is spread by fleas (Table 194-1).

Rickettsiae are important causes of human disease and have, in fact, played a profound effect on human history.[202] This chapter reviews the pediatric manifestations of diseases caused by the spotted fever and typhus groups of *Rickettsia*, *Ehrlichia*, and Anaplasmataceae.

THE SPOTTED FEVERS

The spotted fever group of the genus *Rickettsia* is composed of pathogens that are arthropod borne, mostly by ticks. The exception is rickettsialpox, caused by *Rickettsia akari*, which is a mite-borne infection. Disease produced by *R. rickettsii*, of which RMSF is the prototype, occurs throughout the Americas. There are a variety of other spotted fever illnesses seen around the world, most of which are less clinically severe. These diseases are distinguished by their geography and by variations in the causative organism, but they share their sensitivity to tetracyclines and their obligately intracellular life cycle.

Rocky Mountain Spotted Fever

Historical Aspects. RMSF has an unusually fascinating history. It was originally recognized in the Bitterroot Valley of western Montana, nestled against the Idaho border. According to Howard Ricketts, the first description of "the so-called spotted fever of Idaho" was made

TABLE 194-1 **Classification, Primary Vector, and Reservoir Occurrence of Rickettsiae Known to Cause Disease in Humans**

Antigenic Group	Disease	Species	Vector	Animal Reservoirs	Geographic Distribution
Anaplasma	Human granulocytic anaplasmosis	*Anaplasma phagocytophilum*	Tick	Deer, elk, small mammals, and rodents	Worldwide
Ehrlichia	Human monocytic ehrlichiosis	*Ehrlichia chaffeensis*	Tick	Deer, wild and domestic dogs, domestic ruminants, and rodents	Worldwide
	Ehrlichiosis	*E. muris*	Tick	Deer and rodents	Western United States, Russia, Japan
	Ehrlichiosis	*E. ewingii*	Tick	Deer, wild and domestic dogs, and rodents	North America
Neorickettsia	Sennetsu fever	*Neorickettsia sennetsu*	Trematode	Fish	Japan, Malaysia, possibly other parts of Asia
Scrub typhus	Scrub typhus	*Orientia tsutsugamushi*	Larval mite (chigger)	Rodents	Asia-Pacific region from maritime Russia and China to Indonesia and North Australia to Afghanistan
Spotted fever	Rickettsiosis	*Rickettsia aeschlimannii*	Tick	Unknown	South Africa, Morocco, Mediterranean littoral
	African tick bite fever	*R. africae*	Tick	Ruminants	Sub-Saharan Africa, West Indies
	Rickettsialpox	*R. akari*	Mite	House mice, wild rodents	Countries of the former Soviet Union, South Africa, Korea, Turkey, Balkan countries, North and South America
	Queensland tick typhus	*R. australis*	Tick	Rodents	Australia, Tasmania
	Mediterranean spotted fever or boutonneuse fever	*R. conorii**	Tick	Dogs, rodents	Southern Europe, southern and western Asia, Africa, India
	Cat flea rickettsiosis	*R. felis*	Flea	Domestic cats, rodents, opossums	Europe, North and South America, Africa, Asia
	Far Eastern spotted fever	*R. heilongjiangensis*	Tick	Rodents	Far East of Russia, Northern China, eastern Asia
	Aneruptive fever	*R. helvetica*	Tick	Rodents	Central and northern Europe, Asia
	Flinders Island spotted fever, Thai tick typhus	*R. honei*	Tick	Unknown	Australia, Thailand
	Japanese spotted fever	*R. japonica*	Tick	Rodents	Japan
	Australian spotted fever	*R. marmionii*	Tick	Rodents, reptiles	Australia

	Mediterranean spotted fever–like disease	*R. massiliae*	Tick	Unknown	France, Greece, Spain, Portugal, Switzerland, Sicily, central Africa, and Mali
	Maculatum infection	*R. parkeri*	Tick	Rodents	North and South America
	Rocky Mountain spotted fever, febre maculosa, São Paulo exanthematic typhus, Minas Gerais exanthematic typhus, Brazilian spotted fever	*R. rickettsii*	Tick	Rodents	North, Central, and South America
	North Asian tick typhus, Siberian tick typhus	*R. sibirica*	Tick	Rodents	Russia, China, Mongolia
	Lymphangitis-associated rickettsiosis	*R. sibirica mongolotimonae*	Tick	Rodents	Southern France, Portugal, China, sub-Saharan Africa
	Tick-borne lymphadenopathy (TIBOLA), *Dermacentor*-borne necrosis and lymphadenopathy (DEBONEL)	*R. slovaca*	Tick	Lagomorphs, rodents	Southern and eastern Europe, Asia
Typhus fever	Epidemic typhus, sylvatic typhus	*R. prowazekii*	Human body louse, flying squirrel ectoparasites, *Amblyomma* ticks	Humans, flying squirrels	Central Africa; Asia; Central, North, and South America
	Murine typhus	*R. typhi*	Flea	Rodents	Tropical and subtropical areas worldwide

*Includes four different subspecies that can be distinguished serologically and by PCR assay and respectively are the etiologic agents of boutonneuse fever and Mediterranean tick fever in southern Europe and Africa (*R. conorii* subsp. *conorii*), Indian tick typhus in south Asia (*R. conorii* subsp. *indica*), Israeli tick typhus in southern Europe and Middle East (*R. conorii* subsp. *israelensis*), and Astrakhan spotted fever in the North Caspian region of Russia (*R. conorii* subsp. *caspiae*).

by Edward E. Maxey of Boise City, Idaho, in 1899.[148] The description of the illness, like many clinical characterizations of disease in the pre-laboratory era, was surprisingly consistent with our view today, "an acute, endemic, noncontagious, but probably infectious, febrile disease, characterized clinically by a continuous moderately high fever, severe arthritic and muscular pains, and a profuse petechial or purpuric eruption in the skin, appearing first on the ankles, wrists, and forehead, but rapidly spreading to all parts of the body."[148] The disease was soon recognized throughout the Rocky Mountain states. Whereas there were speculations that ticks were the vectors of RMSF, it was Ricketts who unequivocally proved the association through carefully performed experiments with a guinea pig model of disease. As noted earlier, he died before he was able to identify the causative organism of RMSF with certainty, a step performed by Simeon Burt Wohlbach in 1916. Wohlbach noted that the organism occurred in large numbers in the smooth muscle cells of arteries and veins. There were disputes between Wohlbach and researchers at the Rockefeller Institute in New York as to whether this new small organism was in fact the real pathogen. The dispute was sadly resolved when a laboratory technician working with RMSF at the Rockefeller Institute developed a fever, perhaps after a needle scratch, and died. The technician's blood was transported to Wohlbach's laboratory, where he inoculated guinea pigs and they became symptomatic with characteristic RMSF (in a guinea pig, fever, rash, and vasculitis). Wohlbach chose to name the organism after Howard Ricketts, whom he believed had, in fact, first seen the organism.

Another challenge was to grow the organism, then known as *Dermacentroxenus rickettsii*. It was originally thought that the organism could be grown only in cell cultures,[194] which led to confused debates as to whether the organism was an intracellular bacterium or a virus. The answers came as Herald R. Cox discovered that rickettsiae could be grown in larger numbers in the yolk sacs of fertilized chicken eggs.[39]

Many mysteries remain about certain elements in the natural history of RMSF. For example, the pretreatment mortality rate of RMSF in Idaho was 5 to 7 percent, whereas in the Bitterroot Valley of Montana it was 70 percent.[88] The molecular basis for this difference in virulence remains unclear even today.[35] The epidemiology of RMSF has evolved during the 20th century from being a disease predominantly recognized in the northern Rocky Mountains to a disease most commonly found in a band of contiguous states from Oklahoma to the Carolinas. North Carolina, Tennessee, Arkansas, Missouri, and Oklahoma account for 60 percent of the reported RMSF cases in the United States.[32] The incidence of RMSF has been generally rising, whereas the case-fatality rate has been falling (Fig. 194-1). In 2008, there were roughly 2500 cases of RMSF in the United States, the largest number on record.[32]

Etiology, Morphology, Growth, and Metabolism. *R. rickettsii*, the etiologic agent of RMSF, is a small, nonmotile, pleomorphic, weakly gram-negative coccobacillus measuring 0.3 to 0.5 μm in diameter and 0.3 to 4 μm in length. The cell wall and cytoplasmic membrane are fairly typical for gram-negative bacteria. Rickettsiae must penetrate into living cells to grow and multiply (i.e., they are obligately intracellular). They are grown most readily in the yolk sacs of embryonated eggs; but under special conditions, they also grow well in certain tissue culture

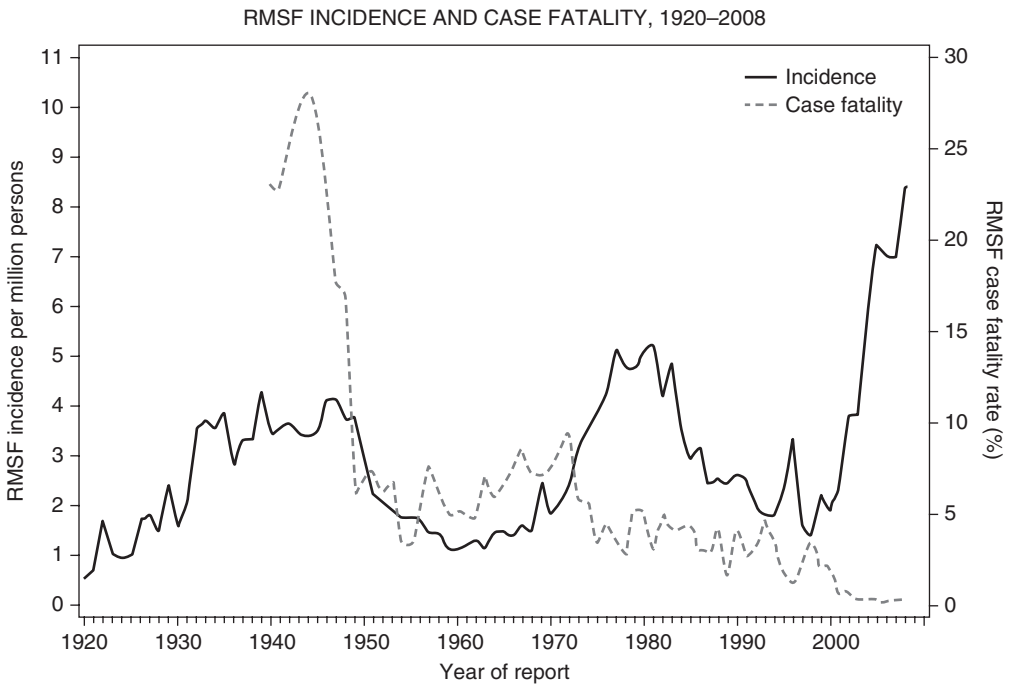

FIGURE 194-1 ■ Rocky Mountain spotted fever incidence and case fatality, 1920-2008. (From Centers for Disease Control and Prevention. Statistics and epidemiology: annual cases of RMSF in the United States. Available at http://www.cdc.gov/rmsf/stats/.)

cells. Once inside a cell, rickettsial cells multiply by transverse binary fission.[78] The organisms lack the intrinsic ability to metabolize carbohydrates and amino acid substrates and derive energy from host adenosine triphosphate (ATP).[35]

Rickettsiae take on a characteristic red color when stained with Gimenez stain. *R. rickettsii* possess a soluble antigenic moiety that is shared with antigenic variants in the spotted fever group and rickettsialpox.

Epidemiology and Transmission. Because *R. rickettsii* is transmitted to people through adult tick vectors, understanding of tick ecology explains much of the epidemiology of RMSF. The vectors for RMSF are *Dermacentor variabilis* (the American dog tick) in the eastern and central United States and *Dermacentor andersoni* (the Rocky Mountain wood tick) in the Rocky Mountain states and West. RMSF has also been reported recently in an area in eastern Arizona where the vector is *Rhipicephalus sanguineus* (the brown dog tick).[32] These ticks prefer woodlands where small rodents share habitats with large domestic and wild animals.[22] RMSF is most common in spring and summer months when ticks are most active.

Regionally, RMSF is concentrated. Fifty-six percent of cases come from five states (North Carolina, South Carolina, Tennessee, Oklahoma, and Arkansas). However, it is widely distributed in North America, and cases have been reported from 46 of the 48 contiguous United States (Maine and Vermont are the exceptions).[34] It tends to occur in hyperendemic foci, and there are reports of family clusters of disease.[28] *R. rickettsii* infection occurs throughout Central and South America via several different tick species; there are a variety of regional names for the infection, such as Tobia fever (Colombia) and São Paolo fever (Brazil).

The life cycle of *Dermacentor andersoni* ticks requires roughly 2 years. In the spring and early summer, adult ticks seek out hosts for a blood meal. Ticks that attach feed for 7 to 9 days, then mate. The engorged females drop off their hosts, laying 5000 to 7000 eggs each. After 35 days, the eggs hatch and the larvae seek out small mammals to which to attach. After 2 to 6 days of feeding, the larvae drop off, mature into nymphs, and become inactive for the winter. In the spring, the nymphs attach to small mammals, feed for 7 days, drop off, hide, and mature into adults. They generally hide for the duration of the summer, fall, and winter and in the spring seek out their adult blood meal.[22]

D. variabilis is similar to the Rocky Mountain wood tick but adapted to the climate of the central and eastern United States. The larvae and nymphs have a narrower host range and show a preference for meadow and white-footed mice. Dogs are the primary hosts for the adult ticks, but the adult ticks are willing to bite a wide range of large mammals, including humans, who are thus an incidental victim. Larvae are most active in the early spring (March and April), then become active again in the late summer (August and September) if they did not successfully feed in the spring. Nymphs are also active in spring and late summer, with the spring nymphs having overwintered and the late summer nymphs a product of spring larvae. Adults also most actively seek blood meals from April to September, although they can become active in any month if the weather is warm enough.[22]

Rickettsiae multiply in ticks and small mammals. The organisms are found in the salivary gland, and during a blood meal the organisms are activated and become more pathogenic. They are ultimately injected into the host by the tick during the course of the blood meal, although ticks can also transmit as they are squeezed during the process of tick removal.[35] Rickettsiae can be passed from one generation of tick to the next transovarially and can persist from hatching into the adult tick. This is particularly impressive because adult ticks can wait up to 4 years for a blood meal. However, infected ticks seem to have a biologic disadvantage, and relatively few *R. rickettsii*–infected larvae ultimately mature into adults.[49] The organisms are found in the salivary glands and the gastrointestinal tract of the ticks. Interestingly, RMSF is also a sexually transmitted disease; it can be spread from infected male ticks to uninfected females through infected spermatozoa.[79,133]

Although it is uncommon, RMSF can be spread through aerosolization in the laboratory, so care should be taken (it requires a biosafety level 3 facility). In addition, there have been uncommon transmissions by transfusion[187] and needle stick accidents.[153]

Seroprevalence studies have demonstrated that subclinical disease may be more common than symptomatic, although it is difficult to know whether the results reflect antibodies to rickettsiae other than *R. rickettsii* or perhaps cross-reactive antigens from other organisms.[191] A large seroprevalence survey of children at sites in the southeastern United States found *R. rickettsii* seropositivity rates that varied from 3.5 percent in Louisville, Kentucky, to 21.9 percent in Little Rock, Arkansas. These are rates that seem high relative to the actual incidence of RMSF. Also noteworthy was the large jump in overall seroprevalence from the 1- to 6-year-old age group (4.2%) to the 7- to 12-year-olds (13.9%), suggesting a higher rate of exposure in early school-age children.[112]

Perhaps because *R. rickettsii* is biologically disadvantageous for ticks, it is relatively uncommon even in highly endemic areas. The tick prevalence of *R. rickettsii* infection is less than one RMSF infection per 1000 ticks, whereas many ticks have nonpathogenic rickettsiae like *Rickettsia montana* or *Rickettsia rhipicephali*.[176] This low prevalence is one of the primary reasons that there is no role for doxycycline prophylaxis after removal of an engorged tick.

Pathogenesis. Vasculitis is the fundamental disease process in RMSF. Rickettsiae infect the endothelial cells lining blood vessels, particularly of small and medium-sized blood vessels, and the resultant cellular damage creates vascular lesions that can involve almost the entire vascular bed. The process begins when the tick bites an individual and begins its blood meal. Rickettsiae are introduced from the salivary glands of the tick, and the infectious cycle begins.

At a cellular level, rickettsiae are internalized by endocytosis into vacuoles. They are initially enclosed in a

vacuolar membrane but are able to degrade the membrane and escape into the cytosol. Rickettsiae are obligate intracellular pathogens, and they require access to the cytoplasm to grow. They lack the ability to metabolize carbohydrates and amino acids and thus obtain their energy from host ATP molecules.[35] Once in the cytoplasm, the organisms replicate by binary fission. They recruit host cell actin molecules, and they use the actin to spread from cell to cell, transported through cell membranes without producing damage. They spread rapidly among the endothelial cells lining the vascular and lymphatic systems. As the cells become injured by the rickettsiae, they lose their attachment to adjacent cells, and the smooth vascular surface becomes increasingly rough and leaky.

The immune response to *R. rickettsia* involves perivascular lymphocytic infiltrates. As the endothelial cells fail, small leaks in the capillary bed produce increased vascular permeability, microhemorrhages, localized edema, and local inflammation. With time, the problem becomes more generalized, involving a wide variety of organs, including the skin, brain, lungs, kidneys, and liver. Eventually the combination of leakage, edema, and inflammation can produce organ failure. On pathologic examination in affected patients, inflammation can be seen in the affected tissues.

Clearance of *R. rickettsii* is predominantly by cellular immunity, including cytotoxic T lymphocytes and interferon-γ. The immune response lyses infected cells, an action that may be the primary means by which rickettsial infection causes cell injury.[176] A broad range of antibodies are produced against *R. rickettsii*, and these antibodies appear to be the host's primary defense against reinfection. Although it is not absolutely certain, it is generally believed that people are not infected by *R. rickettsii* more than once.

The laboratory hallmarks of RMSF are also a product of this diffuse vascular injury, with often profound thrombocytopenia and mild to moderate hyponatremia. The thrombocytopenia is a result of platelet consumption along damaged vascular surfaces; the hyponatremia is probably a combination of shifting of electrolytes from the intracellular to the extracellular space, loss of sodium through excretion, exchange of sodium for potassium at the cellular level, and the syndrome of inappropriate antidiuretic hormone secretion.[92]

The extent of disease is dependent on several factors in addition to the timing of treatment initiation. For example, there is the regional variation noted earlier (Montana vs. Idaho). The inoculum size is almost certainly important and may relate to the duration of tick attachment. Most of the time, *R. rickettsii* in tick salivary glands are in a dormant, noncontagious state. During the blood meal, the rickettsiae become active and virulent, a process that may take as long as 4 to 6 hours. As a result, that duration is thought to be the necessary length of attachment for transmission to occur. Host factors that make RMSF potentially more severe include glucose-6-phosphate dehydrogenase (G6PD) deficiency (a sex-linked condition found in 12% of African American males), age (adults are at higher risk for severe disease), and gender (males more than females).[176]

Clinical Manifestations. The classic manifestations of RMSF are fever, headache, myalgias, severe malaise, and rash. The illness is seldom subtle, and most children infected with *R. rickettsii* appear quite ill. Temperatures in the range of 40°C (104°F) are typical. In the early stages, rash may not be present or may be only pale, erythematous macules. In dark-skinned patients, the early rash may not be apparent. As the illness progresses, the fever persists, the degree of malaise becomes complete prostration, and the rash evolves from macules to petechiae. Eventually, the child can become hypotensive and obtunded and may die if not appropriately treated.

RMSF is transmitted by tick bite, but surprisingly only half of patients can recall being bitten by a tick.[20] This probably reflects the facts that ticks are stealthy and generally obtain their blood meal efficiently, without pain. They may attach in areas that are not easily seen. The consequence for physicians is that the historical review should focus not only on tick bites but also on behaviors that put someone at risk for tick exposure. These behaviors include walking in woods or high grass in the spring or summer or during a sustained warm spell. In terms of RMSF, the degree of regional incidence of *R. rickettsii* infection should also be considered; the southeastern and south-central United States have the highest incidence.

The incubation period for RMSF after the tick bite is 48 hours to 14 days, with a median of 4 days.[20,35] The first symptoms are usually fever, headache, myalgias, and malaise. These are obviously nonspecific findings, making the diagnosis of RMSF difficult. Fever is virtually a sine qua non, occurring in 98 percent of pediatric RMSF cases.[20] Profound malaise is also present from early in the illness, marking RMSF as more than the typical nonspecific virus infection. Sixty percent of children develop a headache, which is often severe. Lumbar punctures typically have a mild leukocytosis, with a median of 25 cells/mm^3.[20]

Rash is not reliably present in the early stages of disease, unfortunately. The rash typically appears in the second to fourth day of illness, which is generally after patients have first sought medical care.[34] Eventually 90 percent or more of children have rash. The early rash begins as faint macules, often on the arms and lower legs. At this stage, the lesions still blanch on pressure. Petechiae evolve during several days. Classically the rash evolves from the periphery toward the trunk and involves the palms and soles. However, neither the centripetal nature nor palm and sole involvement is a definitive or reliable finding. Generalized petechiae are seen around the fifth or sixth day of illness, at which point patients are severely ill. They are likely to have organ system dysfunction, and recovery will be slow even with treatment.[34]

Other common symptoms are myalgia (45% in the Buckingham series[20]), abdominal pain that can mimic appendicitis (36%), diarrhea (34%), conjunctival injection (33%), altered mental status (33%), lymphadenopathy (29%), and peripheral edema (25%). Less common findings include hepatomegaly, photophobia, seizures, meningismus, splenomegaly, periorbital edema, and coma. Of these symptoms, the conjunctival injection and peripheral edema are most likely to point in the direction

of RMSF, although both usually occur in patients who already have extensive rash.

The laboratory findings are also only moderately helpful. As noted in the section on diagnosis, the only true acute diagnostic test is biopsy of petechial or macular lesions and demonstration of the organism by immunohistochemical staining or polymerase chain reaction (PCR) testing. Antibody tests have almost no utility acutely because the immunofluorescent antibody (IFA) assay titers will not rise into a diagnostic range until 10 days or more into the illness, days after treatment should have been started. The two most useful laboratory findings are thrombocytopenia and hyponatremia. Sixty percent of children have a platelet count below 150,000 cells/mm^3 at their initial presentation, and the median platelet count is 128,000 cells/mm^3. In regard to serum sodium, 52 percent have sodium concentrations below 135 mEq/L, with a median concentration of 133 mEq/L. Other laboratory values that can be abnormal include hepatic enzymes (alanine aminotransferase, aspartate aminotransferase), serum bilirubin, hemoglobin, cerebrospinal fluid cell count, glucose, and protein.

Some patients with RMSF have focal cardiac disease, in particular myocarditis, and rare patients have evidence of pneumonia.

Even with treatment, RMSF can leave patients with residual neurologic damage, as described later in the prognosis section. Conditions associated with more severe RMSF, in addition to delayed treatment, include G6PD deficiency and early treatment with sulfa drugs.

Diagnosis. Because the early manifestations of *R. rickettsii* infection are nonspecific, the problem is to diagnose RMSF effectively and to avoid overtreating a multitude of children. In the right season (summer) in an endemic region, this can be a significant challenge. If an error is made, it should be in overtreatment of patients in whom infection is suspected, given the relative risks of undertreatment of RMSF versus the potential for unnecessary exposure to doxycycline.

For confirmation of a diagnosis of *R. rickettsii* infection, the most widely used test is the indirect IFA assay. The sensitivity of this assay is inadequate to be useful in the first 10 to 12 days of illness. There is essentially no value in a negative test result; it does not rule out RMSF and should not be used for that purpose. The value of IFA assay comes to confirm whether an illness was RMSF ex post facto. The test is 94 percent sensitive by 14 to 21 days.[91] The diagnosis requires a fourfold rise in titer between acute and convalescent sera. A "probable" diagnosis is generally made on the basis of a single convalescent IFA titer of 1:64 or greater.

To make a diagnosis of RMSF more acutely, if a patient has a rash, a skin biopsy can be performed to sample petechial lesions. The lesion can be sent for either immunohistochemical staining or PCR testing, depending on availability. Immunohistochemical staining of biopsy material has been found to be 100 percent specific and 70 percent sensitive.[177] It is most useful either before or very early in treatment. PCR is less established as a diagnostic method but can be performed on either tissue or blood.

The other important but nonspecific diagnostic clues pointing toward RMSF are thrombocytopenia, hyponatremia, and the rash. One case series found the average platelet count at presentation to be 128,000 cells/mm^3; forty-one percent had fewer than 100,000 platelets at initial presentation.[20] In terms of sodium, the median sodium concentration at presentation was 133 mEq/L, and 52 percent of children had a serum sodium concentration below 135 mEq/L. The rash, when present, is an important clue, but the absence of rash does not exclude RMSF. As noted before, the rash begins as faint macules, which become petechial as the disease progresses. They may be found on the palms and soles, but rashes in those locations are seen in only two thirds of children.[20]

Differential Diagnosis. Perhaps the greatest challenge to RMSF is making a clinical diagnosis in time for effective treatment. The characteristics that define early RMSF are fairly nonspecific: fever, headache, some photophobia, and severe malaise. The first critical clue is whether the patient has been in an endemic area, although RMSF has occurred in all of the lower 48 states except Maine and Vermont, and whether the season is right (spring, summer, or a recent warm spell). A rash usually appears somewhere between the third and fifth day and can be a helpful clue, but roughly 10 percent of patients with confirmed RMSF never have a rash. Because of the lack of specificity to the symptoms, clinicians must begin with a high level of suspicion. Enteroviral infections (echovirus, coxsackievirus) appear similar to RMSF, have the same summer seasonality, and can produce a similar rash. In endemic regions, the practical reality is that quite a few enteroviral infections are "cured" with doxycycline.

A more problematic overlap is with *Neisseria meningitidis*. The early symptoms of meningococcemia are again similar to RMSF, with fever, headache, and malaise. Laboratory findings may also be similar, with thrombocytopenia and a leukocyte count that reflects a left shift. Because neither RMSF nor meningococcemia can be quickly confirmed, and because both require a rapid initiation of treatment, it is reasonable and appropriate to begin both doxycycline and penicillin (or some other appropriate β-lactam or cephalosporin) until the situation can be sorted out (primarily by blood culture).

The full differential diagnosis for RMSF includes enteroviral infections, adenoviral infections, meningococcemia, influenza, gram-negative bacterial sepsis, toxic shock syndrome, measles, rubella, secondary syphilis, leptospirosis, typhoid fever, disseminated gonococcal infection, immune thrombocytopenic purpura, thrombotic thrombocytopenic purpura, immune complex vasculitis (e.g., systemic lupus erythematosus), infectious mononucleosis, hypersensitivity reaction to drugs, murine typhus, rickettsialpox, recrudescent typhus, and sylvatic *Rickettsia prowazekii* infection that is enzootic in flying squirrels.[176]

During the summer in endemic regions, it is fairly common practice to see patients early in the course of a febrile illness. In the first 2 days of fever, practitioners often obtain screening laboratory tests (a complete blood count and chemistry) and, if the patient does not have severe malaise, opt to watch. If the fever persists into the

third day, if the screening laboratory test results appear suggestive, or if the patient appears to be more ill than is usually the case with a viral illness, treatment with doxycycline is initiated. The worst outcomes with RMSF occur when a physician dogmatically holds to a preliminary diagnosis in the face of persisting illness, often because of the absence of a rash or laboratory test result pointing toward RMSF.

Treatment. RMSF is an easily treatable disease with a good prognosis if treatment is begun suitably early. However, therapeutic failures occur every summer because the diagnosis is not considered. The symptoms can mimic other diseases (e.g., enterovirus infection, meningococcemia, infectious mononucleosis, appendicitis, pharyngitis), prompting inappropriate treatment decisions. If doxycycline is initiated within the first 5 days of fever, the prognosis is excellent. The problem is deciding which patients to treat, which to observe. Even in areas where RMSF is endemic, 60 to 75 percent of patients with RMSF are given an alternative diagnosis at their first clinical visit. The probabilities of morbidity and mortality escalate rapidly with each day of treatment delay.

The other important challenge to treating RMSF is the need to begin treatment before the standard diagnostic test results become definitively positive. At the onset of fever, antibody titers against *R. rickettsii* will almost always be negative. In most cases, the IFA test result becomes positive between 7 and 10 days, and by 14 to 21 days, IFA titers are 94 percent sensitive. However, during the first week, when treatment needs to be initiated, antibody titers will be negative. Even defining who is at risk can be difficult. Because ticks are very good at their profession (blood sucking), in only 50 percent of cases do patients report a time-appropriate tick exposure.[20]

Doxycycline is the primary antibiotic used to treat RMSF. Historically, chloramphenicol was demonstrated to be equally effective, and it remains the only documented alternative treatment, but its side effect profile, particularly in causing aplastic anemia, has made oral chloramphenicol unavailable in the United States. Doxycycline is dosed at 2.2 mg/kg/dose every 12 hours (maximum, 100 mg every 12 hours) for the duration of fever and an additional 3 days (at least 5 days, and typically 7 to 10 days). Once the patient is improving, relapse is highly unlikely, and there is no chronic form of *R. rickettsii* infection. Doxycycline may be given intravenously or orally, depending on the degree of illness. Whereas tetracyclines have been associated with dental staining, doxycycline does not pose a significant risk (particularly in comparison to untreated RMSF).

Severe RMSF can require hospitalization and, at times, advanced life support: intravenous fluids, pressors, and assisted ventilation. In its severe form, RMSF includes a profound vasculitis that can mimic disseminated intravascular coagulopathy, with thrombocytopenia, generalized petechiae, hemorrhages, and shock. In many ways, it clinically resembles meningococcemia.

Whereas some children with RMSF are empirically treated with antibiotics other than doxycycline during the early phases of management, given the already noted similarity to meningococcemia, most of those antibiotics will have no effect on the course of RMSF. The one exception is sulfa drugs, including trimethoprim-sulfamethoxazole, which can make RMSF more severe. The mechanism for this observation is still unclear.[34]

Prognosis. The mortality rate in the modern era for untreated RMSF is 20 percent; for treated patients, it is roughly 5 percent.[34] Interestingly, in the preantibiotic era, the mortality rate for RMSF was highly variable. For example, RMSF in the Bitterroot Valley of Montana had a mortality rate of 75 percent, whereas in the Snake River Valley in southern Idaho it was 3 percent.[3] The reasons for differential rates like these have never been explained.[35] Most of the current mortality is in patients with delayed initiation of doxycycline. For patients treated with doxycycline in the first 5 days of symptoms, the prognosis is excellent.

In children who have had severe RMSF, there is a significant rate of residual problems. In one series, 13 of 89 surviving children were discharged from the hospital with neurologic deficits, including speech and swallowing dysfunction, global encephalopathy, ataxia or gait disturbances, and cortical blindness.[20] Many of the children with long-term follow-up continued to have neurologic problems. Two of the 89 children had loss of digits due to autoamputation.

Prevention. The most effective measures for control of RMSF are personal steps to avoid ticks. Wearing pants tucked into boots or socks is not a fashion statement, but it can be useful in tick avoidance. Permethrin-based insect repellants can be effective, although they should be applied to clothes rather than directly on skin (a caution for which users will be grateful after smelling permethrin-based repellants). Insect repellants containing 20 to 50 percent DEET applied to skin may have some effect, although they are probably more effective in deterring mosquitoes than ticks. Adults should perform regular tick inspections on themselves and on children for whom they are responsible because ticks require 4 to 6 hours of attachment to transmit *R. rickettsii*. Ticks are fond of high grasses, brushy areas, and mixed forests, so care should be taken to stay in the center of well-trodden trails. Pets can be protected with medications or flea and tick collars.[29]

Patients should be taught the art of removing ticks from skin. There are many old wives' tales about how to remove ticks: touching their backs with an extinguished match, applying clear nail polish to suffocate them, applying petroleum jelly. Given the effectiveness of these strategies, the surprise is that there are any old wives left to tell tales. To remove a tick, use tweezers, grasp the tick's head as close to the skin as possible, and twist out. The area should be scrubbed with soap or alcohol because any residual tick spit or fecal material has the potential to be infectious and to contaminate the bite wound. Incinerating a tick after removal is, however, perfectly appropriate, as is the more usual approach of flushing it into the sewer system.

Whereas vaccines against RMSF were in use for many years, they were probably marginally effective, if at all, and are no longer available.

Mediterranean Spotted Fever

Overview. Mediterranean spotted fever (MSF) is a tick-borne infection caused by *Rickettsia conorii*. The disease was first described by Conor and Bruch in 1910,[38] and the name "Mediterranean spotted fever" was adopted in 1932. In the Mediterranean region, this infection is also known as boutonneuse fever and Marseilles fever. Whereas the infection has been recognized for a century, until recently it was regarded as a benign disease. In 1982 the first case report of fatal MSF was published.[140] Its potential lethality has been demonstrated in numerous other studies, including one in which 32.3 percent of hospitalized patients died.[43] It is now regarded as comparable to RMSF in its potential for mortality.

Epidemiology. *R. conorii* infection occurs across a wide geographic swath that includes not only the Mediterranean region but also parts of central and southern Africa, the Middle East, and central and south Asia. Locale-specific names given to this infection include Astrakhan spotted fever, Kenya tick bite fever, African tick typhus, India tick typhus, and Israeli spotted fever. The geographic diversity of MSF is matched by its genetic diversity; there are numerous regional subspecies of *R. conorii* capable of causing human disease.[201] The only known vector is the brown dog tick, *Rhipicephalus sanguineus*. The tick is the only known reservoir as well as the vector for *R. conorii*.

MSF occurs in all age groups of both sexes. The epidemiologic pattern is determined by the biology of the tick; consequently, a consistent seasonal peak occurs from June to October. The incidence of the disease appears to rise and fall periodically. The most recent decades have seen an increase in cases in a number of countries, including Portugal, Italy, France, Spain, Bulgaria, and Algeria.[151]

Clinical Manifestations. The infecting bite is unnoticed in most cases. Conjunctival inoculation occurs occasionally. The incubation period ranges from 6 to 10 days. The primary lesion, tache noire (black spot), described and named by Pieri in the 1920s, develops at the site of the tick bite, is not painful, and is rarely pruritic.[178] It occurs most often on the head in children and on the legs in adults. The lesion develops central necrosis, then an eschar, and regional lymph nodes enlarge. The initial lesion heals slowly and resolves after 10 to 20 days without scarring, although residual pigmentation can persist indefinitely.

Tache noire is pathognomonic but is evident in only 30 to 90 percent of patients. Multiple lesions occur occasionally. Formation of the lesion requires a substance secreted by the tick and another of rickettsial origin; it is not reproduced by a separate bite of an uninfected tick or by experimental inoculation of *R. conorii*. An inflammatory infiltrate, predominantly mononuclear, accumulates at the tache noire site, suggesting the importance of T cell–mediated immunity in local host defense.

The onset of disease usually is abrupt, with malaise and fever that reaches temperatures of 39° C to 40° C (102.2° F to 104° F) within the first 2 or 3 days. The fever continues for 6 to 12 days, but antibiotics can shorten the febrile period. Severe and unremitting headache is a typical feature of the disease in adults.[5] On the other hand, headache occurs in less than one third of pediatric patients.[37] Arthralgia and myalgia, especially of the leg muscles, are prominent features in adults; in children, they are rarely of sufficient severity to restrict mobility.

A maculopapular exanthem that develops on the third to the fifth febrile day is almost universally present. Lesions are present initially on the extremities, spreading within a day or so to the trunk, neck, face, buttocks, palms, and soles. The initial lesions are macular, pink, and irregularly defined but become maculopapular within hours. They generally measure 1 to 4 mm in diameter. The rash persists for 10 to 20 days after the remission of clinical symptoms. It can become purpuric or intensely pruritic. Atypical cutaneous manifestations, such as petechial, purpuric, or papulovesicular rashes, occur occasionally.[37,61]

The cutaneous manifestations of MSF are caused by involvement of the vascular structures of the dermis. Rickettsemia during the incubation period probably seeds the endothelial cells of the capillaries, arterioles, and venules. The vasculitis produced is much like that seen in RMSF. It gradually disappears during convalescence, and as the maculopapules fade, a brown discoloration of the skin may be noticed.

Cardiovascular and respiratory changes are transient and nonspecific. Bradycardia is the most consistent finding, but other dysrhythmias can occur. In more seriously ill patients, pericarditis, heart failure, and myocarditis have developed. Phlebitis of the lower limbs is the main vascular complication. Venous thrombosis is a recognized complication, and pregnant patients are particularly prone to venous thrombosis. Pneumonitis, pleuritis, pleuropericarditis, and adult respiratory distress syndrome have been described in association with MSF.

In addition to the headache that is characteristic of rickettsial illnesses, varying degrees of impaired consciousness can occur. Rarely, stupor, delirium, convulsions, and transient hypoacusis may be noted. Neurologic sequelae have been observed after rickettsial encephalitis.

Renal function is not altered in most cases, although nephritis with acute renal failure has occurred occasionally. The liver is palpable in a third of patients, and the spleen can be enlarged in 20 percent of children. Tests of hepatic function reveal an increase in serum transaminase levels in one fourth to one half of pediatric cases. Alkaline phosphatase levels are elevated in one third of patients. Needle biopsy of the liver reveals foci of hepatocellular necrosis and a predominantly mononuclear reaction to the necrosis at sites of infection by *R. conorii*. The lesion differs from a true granuloma in that it is not an aggregate of epithelioid macrophages.[179]

A variety of other systemic symptoms can occur. Photophobia and bilateral conjunctivitis have been reported. Severe unilateral conjunctivitis suggests that transmission of the disease occurs by the conjunctival route. Uveitis, choroiditis, retinal artery occlusion, and neuroretinitis are uncommon ocular disturbances.[2,46]

Hematologic abnormalities include isolated cases of autoimmune anemia and mixed cryoglobulinemia associated with MSF. Some studies report a high incidence of

hypoproteinemia. Immune complex–mediated vasculitis associated with MSF has been described.[41]

On occasion, MSF can have a malignant, rapidly fatal course, even in previously healthy children. The illness is consistent with a widespread vasculitis characterized by irreversible shock, encephalopathy, disseminated intravascular coagulopathy, and renal failure.[199]

Diagnosis. Rickettsial organisms can be detected by immunofluorescence if biopsy is performed early in the course of disease or by restriction fragment length polymorphism analysis of a PCR product from the tache noire.[118,192] *R. conorii* cannot be isolated from blood cultures by routine laboratory procedures. The clinical findings, geographic location, and epidemiologic considerations help establish the diagnosis.

The diagnosis can be established by one of multiple serologic tests that include complement fixation, latex agglutination, microagglutination, Western blot, and indirect IFA assays.[61,82,169] An IFA assay for *R. conorii* is commercially available. Identification of specific IgM by immunofluorescence can identify acute infection, although some patients with proven MSF treated early with antibiotics have normal antirickettsial IgM levels.

Differential Diagnosis. Before the rash appears, differentiation of MSF from other acute infections is difficult. Even after appearance of the rash, the disease can be confused with measles, meningococcemia, and secondary syphilis. Other rickettsial diseases should be considered, especially in the absence of a tache noire. Cross-reactions among rickettsiae occur with indirect immunofluorescence.

Treatment and Prevention. MSF generally has a benign course, and fatalities rarely occur. Doxycycline is the drug of choice. An alternative regimen is clarithromycin or azithromycin administered orally at a dosage of 15 mg/kg/day in two doses for 7 days and 10 mg/kg once daily for 3 days.[25,37] Use of chloramphenicol or ciprofloxacin also is effective therapy. The optimal duration of specific therapy has not been definitively established, and regimens ranging from single doses to treatment for up to 15 days have been reported.[74]

The major effective methods of control involve avoidance of tick bites. Natural immunity occurs after infection, and antibodies persist for as long as 4 years after acute illness. Effective vaccines are not available.[111]

Rickettsialpox

Historical Aspects. First described in New York City in 1946 by Sussman as "Kew Gardens spotted fever," rickettsialpox is a benign spotted fever group rickettsial disease caused by *Rickettsia akari*.[85,87,163] Reporting of rickettsialpox declined in the latter decades of the 20th century; fewer than 50 cases were reported by the New York City Department of Health between 1980 and 1999. At least 34 cases were confirmed in 2001 and 2002, possibly as the result of increased awareness and detection of the disease after the bioterrorism anthrax attacks of 2001.[127]

The Organism. The etiologic agent, *R. akari*, is an obligate intracellular gram-negative coccobacillus that is morphologically identical to *R. rickettsii*. The principal vector is the house mouse mite, *Liponyssoides sanguineus*. Rodents, particularly the house mouse, *Mus musculus*, serve as a reservoir for *R. akari*.

Epidemiology and Transmission. Most rickettsialpox in the United States has been reported from New York City, but cases also have occurred in many other cities in the United States and worldwide in Russia, Korea, and South Africa. Whereas house mice are the natural hosts of the mite transmitting rickettsialpox in the United States, rats have been shown to host the mite in Russia, and wild rodents are suspected of carrying the disease in South Africa. The reservoir for rickettsialpox may extend to additional, as yet unidentified, wild or domestic animals.

The disease has a natural cycle between the mite vector and the house mouse.[86] The mite passes the disease transovarially, so it is both a reservoir and vector. Humans acquire infection when depletion of mouse hosts caused by reduced availability of food, poison, disease, or trapping forces infected mites to seek an alternative host, namely, people. The disease affects persons of all ages. Males and females are equally susceptible.[19,73]

Pathology. Biopsy specimens from eschars are characterized by variable degrees of epidermal and dermal necrosis. Ulcerated lesions typically have neutrophils and thrombosed vessels in the ulcer base. The primary pattern of inflammation is a deep perivascular mononuclear cell infiltrate. Immunohistochemical staining reveals spotted fever group rickettsiae predominantly within the macrophages or mononuclear cells of the perivascular infiltrates associated with eschars or papules.[99]

Clinical Manifestations. The incubation period of rickettsialpox is 9 to 14 days after the usually painless mite bite occurs.[19,93] The primary lesion is a papule that develops at the site of the mite bite. This lesion progresses through a papulonodular stage to a tense 0.5- to 2-cm vesicle that ruptures to form an eschar with surrounding induration, which is the hallmark of the disease.[152] Two eschars may be seen. Regional lymph nodes related to the primary eschar are almost invariably enlarged.

Constitutional symptoms develop approximately a week after the mite bite. Fever and malaise are commonly present. The fever is irregular, with temperature fluctuating between 37.8°C and 39.5°C (100°F and 103°F), and rarely lasts longer than 6 or 7 days. It usually is accompanied by the frontal headache characteristic of rickettsial diseases. Rhinorrhea, cough, sore throat, nausea, vomiting, and abdominal pain are occasional findings.[72]

The rash is the most remarkable aspect of the disease. It usually develops within several days of the onset of fever as scattered nonpruritic macules, which rapidly become firm maculopapules. Within a day or two, vesicles develop on the summits of the papules. The lesions usually appear on the face, trunk, and extremities, with

sparing of the palms and soles.[18] The number of lesions ranges from 5 or 6 to more than 100.

Diagnosis. The diagnosis can be made by immunohistochemical staining of skin biopsy specimens, by PCR analysis of amplified gene products from eschars or culture of *R. akari* from eschars, and by serologic assays. These tests, used singly or in combination, to establish the diagnosis are available through the Centers for Disease Control and Prevention (CDC). A fourfold increase in serum antibodies to *R. akari* between acute and convalescent sera or a single titer of more than a 1:64 dilution is considered diagnostic. Cross-reaction is seen between antibodies to *R. akari* and *R. rickettsii*, but titers are greater with *R. akari* than with *R. rickettsii* antigen.[127]

Differential Diagnosis. Anthrax is a differential consideration. Rickettsialpox lacks the striking brawny, nonpitting edema surrounding the eschar that is characteristic of anthrax. Anthrax is not associated with the characteristic papulovesicular rash of rickettsialpox. The haphazard distribution of the characteristic papulovesicles is similar in appearance to chickenpox rash in an adult. Infectious mononucleosis, gonococcemia, and infection with echovirus or coxsackieviruses also should be considered.[106] Patients often give a history of having worked in basements, around incinerators, or in similar areas that might be infested by house mice and their mites.

Treatment. Rickettsialpox is a self-limited nonfatal disease that resolves within 7 to 10 days in untreated patients. Treatment shortens the duration of symptoms, usually to 24 to 48 hours.[19] Doxycycline is the drug of choice. A treatment course of 3 to 5 days is sufficient.

Other Spotted Fever Group Rickettsioses

A number of antigenically distinct *Rickettsia* spp. cause disease in humans. Among these, *Rickettsia parkeri* is perhaps the most important emerging rickettsial disease in the United States. This organism produces a mild spotted fever illness that may be difficult to clinically distinguish from mild RMSF.[126] In contrast with RMSF, an eschar is an important feature of *R. parkeri* infection. The vector for *R. parkeri* is the Gulf Coast tick, *Amblyomma maculatum*, which is most heavily concentrated in Gulf Coast and southeastern states. Whereas most cases occur in the Deep South, both infected *A. maculatum* ticks and at least one human case of *R. parkeri* infection have been reported from Virginia.[62,189,198] Serologic assays in clinical use cannot distinguish *R. parkeri* from *R. rickettsii*. Whereas *R. parkeri* infection may be self-limited, it would be prudent to treat all suspected *R. parkeri* cases as if they are RMSF.

Another notable member of the spotted fever group is *Rickettsia africae*, the cause of African tick bite fever (ATBF). Evidence suggests that this is one of the most common acute febrile illnesses experienced by travelers to Africa.[90] This disease has primarily been associated with travel to southern Africa and in particular travel in the game parks in this part of the continent.[63,139] Its known range is broader, however, and includes much of sub-Saharan Africa. It is also endemic on some eastern Caribbean islands. Cattle ticks from the genus *Amblyomma* are responsible for transmission of the organism. The clinical hallmarks of ATBF are fever, headache, neck muscle myalgias, and an inoculation eschar with regional lymphadenopathy. Up to 50 percent of patients have multiple eschars that ascend along the lymphatic drainage.[105] Rash is unusual in ATBF. This is a benign infection and is probably self-limited in most cases. Doxycycline has been associated with rapid resolution.

Many other *Rickettsia* species are known to infect humans. *Rickettsia japonica* is the etiologic agent of Japanese spotted fever, *Rickettsia sibirica* of Siberian tick typhus, and *Rickettsia australis* of Queensland tick typhus. Dogs are the principal mammalian reservoir; ticks also act as reservoirs by virtue of transovarial transmission. Other newly recognized tick-borne diseases, such as *Rickettsia slovaca* infection, for which the wild boar is the main host, have been described in Europe.[15] *Rickettsia felis* is transmitted by fleas, and its natural reservoirs are the opossum and the cat.[17] The diseases caused by these and other rickettsial species have similar clinical, pathologic, and epidemiologic patterns. As with other rickettsioses, doxycycline is the preferred therapy.

TYPHUS

The rather imprecise term *typhus* is most commonly used to refer to three rickettsial diseases: epidemic typhus, murine or endemic typhus, and scrub typhus. Whereas the respective agents of epidemic and murine typhus, *Rickettsia prowazekii* and *Rickettsia typhi*, are phylogenetically related, scrub typhus is caused by *Orientia tsutsugamushi*, which is not even a member of the genus *Rickettsia*. To make matters more confusing, various spotted fevers are referred to as tick typhus (e.g., Queensland tick typhus, Siberian tick typhus).

Rickettsia prowazekii Infection (Epidemic Typhus)

Overview. Epidemic typhus is a louse-borne infection caused by *R. prowazekii*. Conditions of squalor and overcrowding have resulted in explosive epidemics of typhus in modernity. Typhus has been the suspected cause of some human epidemics dating back to the Dark Ages, but the first known epidemic occurred in 1489 during the Spanish siege of Moorish Granada. In subsequent centuries, most outbreaks have struck during times of war. Outbreaks of typhus occurred throughout the world during the 19th century, famously ravaging Napoleon's army as it retreated from Moscow. Typhus afflicted thousands of soldiers during World War I, particularly on the eastern front. A devastating outbreak struck Russia during its civil war between 1917 and 1925, afflicting an estimated 25 million people and killing 3 million. During World War II, typhus killed tens of thousands as a result of the deplorable conditions in the Nazi ghettos and concentration camps; typhus also struck

soldiers in the North African and Eastern European theaters of war.

The use of dichlorodiphenyltrichloroethane (DDT) in the 1950s resulted in a dramatic worldwide decline in typhus. Since then, it has reemerged predominantly in highland regions of sub-Saharan Africa and to a lesser extent Central and South America. Rwanda, Burundi, and Ethiopia have been particularly affected, certainly as a result of the coexistence of poverty and war.[130] In 1997 approximately 100,000 persons in Burundi were affected and as many as 15 percent died.[13,142,144] A smaller outbreak occurred in Russia in 1997.[167] Although autochthonous cases in the United States are rare, there have been at least 30 cases since 1976. These are most likely due to exposure to the flying squirrel (*Glaucomys volans*), which is a sylvatic reservoir for *R. prowazekii*.[48,116,146]

Epidemiology and Transmission. Humans are the primary reservoir for *R. prowazekii*. Persons who recover from typhus can become a reservoir of *R. prowazekii* in interepidemic periods. This is particularly true in persons with Brill-Zinsser disease, a form of relapsed typhus that can occur many years after the original infection.[68] The best established natural reservoir for *R. prowazekii* is the flying squirrel, *Glaucomys volans*. Lice that infest these animals will not bite humans, suggesting that human infection results from direct exposure to aerosolized louse feces.

The human body louse, *Pediculus humanus corporis*, is the vector for epidemic typhus. The human body louse inhabits clothing, from which it will take blood meals from its host. It is sensitive to dehydration, and frequent blood meals are required. It is also sensitive to both high and low deviations from normal human body temperature. Cold conditions, in which humans have more clothing and blankets, will increase louse habitat. Lice will not survive for long away from a suitable host, so impoverished persons who do not have changes of clothing will be most heavily parasitized. Lice will proliferate under these conditions, and a single person may be infested by thousands of lice. Under crowded and unhygienic conditions, lice will readily pass between people. A heavily infested person who develops typhus can infect thousands of lice, which will promptly seek a new host once fever develops. Because each infected person can secondarily infect many others, there can be explosive epidemic potential under conditions of both high human density and high louse density.

R. prowazekii incubates in the louse for 5 to 10 days after it bites an infected person. Great numbers of rickettsiae are then shed in louse feces.[143] Because the louse defecates as it feeds, infectious feces can be rubbed into a louse bite wound. The bodies of crushed lice are also infectious. Dried louse feces can be aerosolized and cause infection through the eye or the respiratory tract.

Pathogenesis. The organism initially spreads through lymphatics and hematogenously to infect endothelial cells of small blood vessels in a wide variety of target organs.[9] Intracellular proliferation of the organism results in mechanical cell lysis, producing widespread vasculitis and capillary leak.

Clinical Manifestations. Illness begins after a 10- to 14-day incubation period. An initial period of malaise is followed by high fever, headache, and rash.[9] Body temperature generally rises rapidly to 40°C (104°F) or higher. In untreated patients, it remains at this level with minor fluctuations until death or recovery occurs. Headache is common and may be severe or intractable. Cough is also a frequent complaint. The rash usually appears on the trunk by the fourth to seventh day; it spreads peripherally to the extremities and typically spares the face, palms, and soles. Initially, the rash consists of macules that fade on pressure; they soon become fixed as maculopapules and later become petechial or hemorrhagic. Rash is less frequently recognized in individuals with dark skin. Central nervous system manifestations are described in up to 80 percent of patients, including delirium, coma, seizures, and hearing loss.[65] Other complications include parotitis, otitis media, pericarditis, myocarditis, pericardial effusion, pleural effusion, and pneumonia.[45,195,196] Severe cases of typhus can be manifested with shock or with tissue ischemia, including gangrene. Mortality was as high as 60 percent in the preantibiotic era and is higher in malnourished populations and the elderly. With appropriate antibiotics, the mortality is approximately 4 percent. Recrudescent infection (Brill-Zinsser disease) can occur years after the primary infection if it is not eradicated. Partial immunity attenuates the severity of Brill-Zinsser disease.

Diagnosis. Typhus is diagnosed by evidence of seroconversion. A fourfold rise in IgG antibody titer is considered diagnostic. This requires paired acute and convalescent sera. Several testing methods are available, but the preferred method is indirect IFA assay.[102,124] IFA assay will not discriminate epidemic from endemic typhus; discrimination between the two infections requires Western blotting with cross-adsorption.[103] Shell vial culture can detect *R. prowazekii* from blood specimens.[12] The Weil-Felix agglutination test is no longer recommended because of lack of specificity (due to cross-reactivity) and poor sensitivity in Brill-Zinsser disease.

Differential Diagnosis. Typhus may be difficult to distinguish from other acute febrile illnesses, especially early in the course of disease. Depending on the local epidemiology, these can include typhoid fever, dengue, malaria, influenza, leptospirosis, and other rickettsial illnesses. The rash of louse-borne typhus begins centrally on the trunk and spreads peripherally to the extremities, whereas the reverse is true for RMSF. Moreover, a rash on the palms and soles, a common event in RMSF, rarely is observed in typhus.

Treatment. Doxycycline is the treatment of choice for epidemic typhus.[100] Therapy is given until the patient is afebrile for at least 3 days and clinical improvement is evident; the usual duration is 7 to 10 days. Lack of defervescence after 3 days suggests an alternative diagnosis.

Single-dose therapy with doxycycline 200 mg has been effective in epidemic settings.[131] Chloramphenicol is an alternative agent for those with a serious contraindication to doxycycline. As with other rickettsial infections, the risk of tooth staining is negligible for young children receiving this degree of doxycycline exposure; moreover, the potential lethality of typhus justifies the use of doxycycline in children in whom the diagnosis is plausible. Whereas fluoroquinolones have in vitro activity, there has been a treatment failure with ciprofloxacin resulting in death.[200]

Prevention. DDT was effective at limiting the burden of typhus in the 1950s. Its use has been long banned by many countries. Along with DDT, malathion and permethrin are also effective at eradicating lice from infested clothing and bedding. Lice will die within days if they do not have access to a host, so removal of infested clothing for 1 week may suffice.[143] Relief workers assisting persons at risk for typhus can pretreat their clothing with permethrin. Doxycycline prophylaxis appears to be effective in select populations at risk for scrub typhus; whether this is true for epidemic typhus remains unknown.

Rickettsia typhi Infection (Murine Typhus)

Overview. Murine typhus, also known as flea-borne or endemic typhus, is a flea-borne zoonosis primarily of rats, opossums, and cats. The disease occurs worldwide, especially in warm climates where rats or opossums are abundant. During the early 20th century, there were thousands of annual cases of murine typhus in the United States, particularly along the Gulf Coast and the southern Atlantic seaboard. In recent years, 60 to 80 cases have been reported annually, most of which are from southern California, the southeastern Gulf Coast including Texas, and Hawaii.[8,58] The actual incidence in the United States is unknown. Approximately 0.6 percent of children in south-central states have an *R. typhi* titer of greater than 1:64.[113] The seroprevalence in southeastern Texas may be as high as 15 percent. These figures suggest that murine typhus is considerably underrecognized in certain regions.[58,137,190]

Epidemiology and Transmission. *R. typhi* infection is a vector-borne zoonosis that persists in a flea-mammal cycle in nature. The classically described cycle involves the Oriental rat flea, *Xenopsylla cheopis*, and peridomestic rats. Rat infestations, especially near granaries and ports, pose a risk for human contact. A more recently described transmission cycle involves the cat flea, *Ctenocephalides felis*, and opossums or domesticated cats as their primary mammalian host. This cycle seems primarily responsible for ongoing transmission of both *R. typhi* and *R. felis* in suburban regions of southern California and south Texas.[1,16,157] Uninfected fleas acquire the organism from infected mammals and can transmit it to new hosts, including humans; in turn, an infected mammal can serve as a reservoir for many fleas. Rickettsiae multiply and reside in both the digestive and reproductive tracts of the flea, which is unaffected by the organism. The flea goes on to produce highly infectious feces for the rest of its life. It can also pass the organism transovarially to its offspring. Humans are not the preferred hosts for fleas, but the cat flea in particular will readily bite humans. If the flea bites a person, infection typically occurs when flea feces is rubbed into the bite wound; it can also be inoculated by direct contact or by aerosol to mucous membranes.

Clinical Manifestations. Murine typhus is clinically similar to epidemic typhus (*R. prowazekii* infection), but it is milder, of shorter duration, and less likely to be severe or fatal. Symptoms develop after a 5- to 10-day incubation period, although an antecedent flea bite is not always reported. All affected patients develop fever, and the majority have headache or rash.[188] The classic triad of fever, headache, and rash occurs in half of patients. This may be because rash typically appears between days 3 and 10 of illness and may not be present when patients first seek medical attention. Other common symptoms include malaise, myalgias, and vomiting. Rashes are typically macular or maculopapular; only in rare cases have they been described as petechial. Laboratory abnormalities are inconsistently reported, but the most common include elevated hepatic transaminases and mild hyponatremia.[58,157] Children who receive appropriate antibiotics undergo defervescence in 1 to 3 days. Even without appropriate treatment, murine typhus is generally self-limited, with recovery in 1 to 2 weeks and a very low rate of complications.[58,157]

Diagnosis. A fourfold change in titer between acute and convalescent sera by indirect IFA assay, latex agglutination, complement fixation, or enzyme immunoassay is diagnostic. Differentiation among antibodies produced in response to epidemic typhus is difficult but may be accomplished by use of an IgM-specific enzyme immunoassay, if needed. Immunohistochemical staining or PCR analysis of amplified gene product of tissues and culture, available through the CDC, also can be used for confirmation.

Differential Diagnosis. Murine typhus is an undifferentiated acute febrile illness and resembles numerous other infections. In the United States, these include but are not limited to enteroviral disease, other viral exanthems, other rickettsial diseases, and group A streptococcal infection. A history of recent travel to tropical or developing countries could expand the differential diagnosis to include other febrile illnesses, such as malaria, dengue, typhoid fever, and leptospirosis.

Treatment. Doxycycline is the treatment of choice for murine typhus. Chloramphenicol is an alternative in patients with an important contraindication to tetracyclines. Whereas fluoroquinolones have been used successfully to treat *R. typhi* infection, at least one treatment failure has been documented.[104,161] Treatment should be continued for at least 3 days after defervescence and evidence of clinical improvement; this is typically 3 to 7 days.

Prevention. Rat control measures can lower the likelihood of human disease in areas where *R. typhi* is transmitted.

Scrub Typhus

Overview. Scrub typhus is a chigger-borne rickettsial disease caused by *Orientia tsutsugamushi* that exclusively occurs in the Asia-Pacific region. This infection may have been recognized as early as the 3rd century AD and was the subject of non-Western medical writing in Japan during the 19th century.[120] Scrub typhus affected more than 16,000 Allied soldiers in the South Pacific theater of World War II and was second only to malaria as a cause of fever.[120,134] It was also an important pathogen among febrile American soldiers in the Vietnam conflict.[10,80]

The Organism. The causative organism, *O. tsutsugamushi*, was formerly a member of the genus *Rickettsia*. In 1995 it was reclassified to the novel genus *Orientia* on the basis of distinctive phenotypic and genetic features.[165] *O. tsutsugamushi* is distinguished by remarkable antigenic heterogeneity. Strain differences also appear to contribute to striking differences in the severity of scrub typhus.

Epidemiology and Transmission. Scrub typhus is widely distributed throughout central, eastern, and southern Asia. It is transmitted as far north as Kamchatka in eastern Russia and as far west as Pakistan and Afghanistan. Its southern range includes the islands of Indonesia and Oceania as well as northern Australia.[94] The disease is distributed according to the habitat of its vectors, which in turn are distributed in widely diverse habitats. Scrub typhus has been described from sea level to alpine meadows above 3000 meters in elevation, in both arid and humid environments, in a variety of agricultural regions, and more recently in cities.[154,162,173,174] Humans are most likely to encounter chiggers in undergrowth in rural areas. Travelers engaged in outdoor activities, such as camping and trekking, are at risk for acquiring scrub typhus; some of these individuals do not become clinically ill until after return to their home country.[83,154]

Trombiculid mites from the genus *Leptotrombidium* are the vectors for scrub typhus. Only the six-legged larvae, known colloquially as chiggers, will feed on humans. The eight-legged nymphs and adults feed on plant matter and do not parasitize mammals. Wild rodents, particularly rats, are the preferred host for chiggers and are important in the ecology of scrub typhus. The rodents, however, are not thought to be a natural reservoir for *O. tsutsugamushi*, and in fact each mite feeds on a mammalian host only once in its life. Rather, the microorganism persists transstadially (across life cycle stages) within the mite and is passed transovarially to subsequent generations.[64,164,180] Thus, the mite itself is the natural reservoir for this infection.

Pathogenesis. *O. tsutsugamushi* primarily infects endothelial cells and mononuclear leukocytes. Human autopsy specimens have shown endothelial cells infected with microorganisms in numerous organs, including brain, heart, kidney, and lung.[119] They were also found in both macrophages and cardiac muscle cells. The importance of mononuclear leukocytes in scrub typhus has been elucidated in recent years. Dissemination from the inoculation site to target organs may occur through infected peripheral blood mononuclear cells.[182] Infection of monocytes also induces a robust inflammatory cascade that may be responsible for tissue injury and both systemic and organ-specific disease manifestations.[98,166] Marked differences in disease severity and mortality have been noted, and these are attributed to strain variation within *O. tsutsugamushi*. The phenotypic factors responsible for this variability are poorly understood.

Clinical Manifestations. In half to two thirds of cases, the initial mite bite lesion develops into a necrotic eschar. The preferential site for eschar distribution in adults is truncal[96]; in children, eschars are seen commonly in moist intertriginous areas such as the genitalia and perineum.[156] The incubation period is approximately 1 to 2 weeks, and characteristic features of the disease develop at approximately the same time that the eschar is noted. After regression of the eschar, a scar often remains and has been shown to persist for up to 25 years.[186]

Aside from fever, the most consistently described signs in scrub typhus are hepatomegaly, respiratory distress, and lymphadenopathy. In a contemporary prospective report of scrub typhus in 30 children presenting with febrile illness of at least 5 days' duration in Thailand, common physical signs included lymphadenopathy (93%), hepatomegaly (73%), eschar (68%), conjunctival hyperemia (33%), maculopapular rash (30%), interstitial pneumonia (30%), and splenomegaly (23%).[156] In a separate series of 60 Sri Lankan children, the most common findings in patients with confirmed scrub typhus were hepatomegaly (95%), lymphadenopathy (60%), respiratory distress (45%), and splenomegaly (35%).[42] Hepatomegaly was observed in 80 percent and cough in 73 percent of Indian children with scrub typhus.[128] The lymphadenopathy is generalized and is especially prominent in the axilla, neck, and inguinal areas. Myocarditis, disseminated intravascular coagulation, and the acute respiratory distress syndrome are among the complications that can be seen.[121,128] Nervous system disease can be manifested as aseptic meningitis, meningoencephalitis, or cranial or peripheral neuropathies. The severity of the clinical manifestations varies widely, and the lethality of scrub typhus varied even in the preantibiotic era.

Diagnosis. The mainstay of scrub typhus diagnosis is serologic testing. The "gold standard" is the indirect IFA assay; however, there is little consensus in IFA methodology and positivity cutoff limits. Blacksell and colleagues reviewed the evidence base for various methodologies and the criteria for positive IFA assay results and concluded that the diagnosis should be based on a fourfold or greater increase in the IFA titer in paired serum specimens and on a single sample only when there is an adequate local evidence base.[14] The limited number of source strains used for IFA assay antigen may be inadequate given the enormous antigenic diversity and geographic heterogeneity of *O. tsutsugamushi*.[94]

Other tests, such as enzyme-linked immunosorbent assay, dot immunoassay, indirect immunoperoxidase, and Weil-Felix OX-K assay, are also used.[89,122] The last is the most commonly used diagnostic modality in developing countries; however, this assay lacks both sensitivity and specificity. OX-K agglutinins develop in only a little more than 50 percent of scrub typhus patients. Moreover, OX-K agglutinins also are produced in relapsing fever.

Identification of the rickettsial strain in infected patients by use of strain-specific monoclonal antibodies in an inhibition enzyme-linked immunosorbent assay or PCR with strain-specific primers offers potential to establish the diagnosis in the acute stage of the illness.[66,67] An eschar PCR assay, evaluated prospectively, demonstrated high sensitivity and specificity compared with IFA assay.[95] Cell culture and xenodiagnosis-based assays are expensive and laborious and are not available clinically.

Differential Diagnosis. Scrub typhus can be suspected when a patient gives a history of recent exposure in a geographic area where scrub typhus occurs. If, in addition, a local eschar, evanescent rash, and general and regional lymphadenopathy along with fever, headache, and conjunctival suffusion are present, the physician should be alerted to suspect scrub typhus; however, it cannot be differentiated with certainty from other febrile illnesses that occur in the region. These include but are not limited to dengue, chikungunya, leptospirosis, malaria, typhoid fever, and other rickettsioses such as murine typhus.

Treatment. Doxycycline is the treatment of choice. Children have responded well to treatment for 4 to 7 days.[156] Doxycycline is rickettsiostatic, and patients with scrub typhus who are treated in the first week of illness can require sporadic short courses of antibiotic therapy for prevention of relapse.[175] Chloramphenicol, azithromycin, and rifampin are alternatives.[97,129,135] Strains with reduced susceptibility to antibiotics have been observed in northern Thailand.[183] In one study from this region, rifampin was found to produce a significantly faster clinical response than did doxycycline.[184]

Prognosis. The prognosis varies widely because of significant differences in the severity of disease caused by different strains in different populations and in various geographic areas. Mortality rates in the preantibiotic era ranged from 1 to 60 percent. With the use of antimicrobials, fatalities rarely occur. When treatment is begun early in the course of scrub typhus, relapses as well as definite second attacks of the disease can occur. The heterogeneity of scrub typhus strains probably accounts for reinfections.

Prevention. Vector control involves impregnating clothing and smearing exposed skin surfaces with dimethyl or dibutyl phthalate. Short-term vector control of camping grounds can be accomplished by cutting, burning, or bulldozing vegetation, along with heavy spraying with insecticides such as lindane. Chemoprophylaxis is feasible for persons with high-risk exposure for short periods. Doxycycline given once a week provides effective chemoprophylaxis against naturally transmitted scrub typhus if the prophylaxis is started before exposure to infection and continued for 6 weeks after exposure.[175] No satisfactory vaccine has been produced.

EHRLICHIOSIS AND ANAPLASMOSIS

Overview. Ehrlichiosis and anaplasmosis are tick-borne infections caused by rickettsial organisms from the genera *Ehrlichia* and *Anaplasma*. Strictly speaking, they are best thought of as anaplasmoses because both genera are members of the family Anaplasmataceae of the order Rickettsiales. Six members of this family are known to infect humans: *Ehrlichia chaffeensis*, *Ehrlichia ewingii*, *Ehrlichia canis*, *Ehrlichia muris*–like, *Anaplasma phagocytophilum*, and *Neorickettsia sennetsu*. The last two were formerly members of the genus *Ehrlichia*; *A. phagocytophilum* was reclassified to its own genus in 2001.[51]

Unlike many rickettsial infections, which have been recognized for decades if not centuries, ehrlichiosis and anaplasmosis are emerging diseases that have been only recently identified. From 1953 until the late 1980s, the only known human infection from this group was Sennetsu fever, a mild febrile illness in East Asia caused by *Neorickettsia* (formerly *Ehrlichia*) *sennetsu*. The disease that ultimately became known as human monocytic ehrlichiosis (HME) was first described in humans in 1986, and it was suspected that this was due to *E. canis*, a known veterinary pathogen.[55,109] It was not until 1991 that its primary cause, *E. chaffeensis*, was identified.[4] Human ehrlichiosis can also be caused by *E. ewingii*, *E. canis*, and an *E. muris*–like organism.[21,136] In the early 1990s, the syndrome now known as human granulocytic anaplasmosis (HGA) was identified in the upper Midwest; its cause, *A. phagocytophilum*, was recognized in 1994.[36]

The Organisms. *Ehrlichia* and *Anaplasma* are small gram-negative obligately intracellular bacteria. *E. chaffeensis* propagates in macrophages; *A. phagocytophilum* and *E. ewingii* multiply in neutrophils.

Epidemiology and Transmission. The incidence for both HME and HGA has increased substantially during the last decade, although this may be partly a function of increased recognition. These infections have also been reportable only since the late 1990s, which suggests that some of the increased incidence is a function of more complete reporting and case ascertainment practices. There is also annual variation in the incidence of both diseases, which lacks a satisfactory explanation. Nonetheless, hundreds of persons are affected annually. In 2009 there were 944 cases of HME and 1161 cases of HGA.[33] In 2010 there were 740 cases of HME and 1761 cases of HGA. The prevalence of *E. chaffeensis* titers of 1:160 or higher was 3 percent among children residing in the southeast and south-central regions of the United States, suggesting that exposure is far more common than is the incidence of recognized disease.[114]

The geographic distributions of both HME and HGA are tied to the distribution of their respective tick vectors.

The lone star tick, *Amblyomma americanum*, is the principal vector of HME and *E. ewingii* ehrlichiosis. This aggressive tick is by far the most common "pest" tick in the southern and southeastern United States.[23,56,70,117] In low numbers, its range extends as far north as New England, but it is particularly abundant in Missouri, North Carolina, and states farther south. All active stages of the tick will readily bite humans. Individuals can become multiply parasitized by larval ticks (known colloquially as seed ticks). The adult female tick is easily recognized by a conspicuous light-colored spot, but this marking is not present on males or on immature ticks. HME is transmitted in the eastern half of the United States, from the Great Plains to the Atlantic Coast. Oklahoma, Arkansas, and Missouri together account for 35 percent of all cases.[27] Southeastern and mid-Atlantic states account for the majority of the remainder, but HME acquisition is well documented in Delaware and New Jersey and occasionally occurs even in coastal New England. There is also serologic evidence of HME transmission in Central and South America. The white-tailed deer is the most likely natural reservoir for *E. chaffeensis*.[107]

HGA, by contrast, is transmitted in North America, Europe, and Asia. In the United States, it primarily occurs in northeastern states, from New Jersey through northern New England, as well as in Minnesota and Wisconsin in the upper Midwest.[27] The black-legged or deer tick, *Ixodes scapularis*, is the vector for HGA. *A. phagocytophilum* is maintained in nature in a tick-mammal cycle that primarily involves small rodents.[26,168] Whereas adult *I. scapularis* ticks will occasionally feed on humans, it is primarily the nymph whose feeding habits make it a vector for human infections. The nymph is most active in late spring and early summer. Because this immature stage of the tick is quite small, a tick bite often will go unrecognized. HGA shares a vector with Lyme disease, and there is evidence that the endemic range for Lyme disease is expanding; this may portend further expansion of the anaplasmosis-endemic zone as well. HGA is rarely acquired in California, where the Western black-legged tick (*Ixodes pacificus*) is the responsible vector. In Europe, it is transmitted by *Ixodes ricinus*; in Asia, its vector is *Ixodes persulcatus*.

Both anaplasmosis and ehrlichiosis are predominantly transmitted from May through October, in conjunction with the peak activity of their tick vectors. In contrast to other tick-borne diseases such as Lyme disease and RMSF, in which children have among the highest incidence rates, it is older adults who suffer the highest incidence of HGA and HME.

Pathogenesis and Pathology. The pathogenesis of ehrlichiosis is incompletely elucidated. Although it is capable of establishing infection in numerous organs and tissues, the primary target cell for HGA is the granulocyte; for HME, it is the macrophage. Granulomas of the bone marrow occur frequently in HME, suggesting that involvement of the reticuloendothelial system may be important in pathogenesis.[52]

Organisms enter the cytoplasm of host cells and proliferate in phagosomes into elementary bodies. These individual organisms multiply by binary fission into immature inclusions called initial bodies. Mature groups of elementary bodies form morulae, which are released by rupture of the cell to reinitiate the infecting process.[109]

Clinical Manifestations. Most patients become clinically ill within 2 weeks of exposure. HME and HGA are acute febrile illnesses in which fever and malaise are universal symptoms.[50,53,60,132] Headache, myalgia, arthralgias, and nausea are also common. Confusion occurs in about 20 percent of patients with HME, primarily among older adults; this symptom is less common in HGA. Rash is more common in ehrlichiosis than in anaplasmosis and primarily occurs in children. Rashes can be macular, maculopapular, or petechial and seldom develop in adult infections. Rashes are reported in about 30 percent of cases of HME, compared with 10 percent or less in HGA.

Meningitis as a manifestation of HME has been reported in children. Symptoms can range from irritability and meningismus to obtundation with response only to painful stimuli.[11,47,71] Initial examination of cerebrospinal fluid reveals pleocytosis ranging from approximately 50 to 1400 white blood cells, usually with a predominance of mononuclear cells; a range of 5 to 40 red blood cells; mildly elevated protein concentration; and a normal to slightly low glucose value. Complete recovery is the rule. Central nervous system involvement is much less common in HGA.

The most common laboratory findings in both infections are hematologic abnormalities and elevated hepatic transaminases.[50] Thrombocytopenia is seen in three quarters of patients, leukopenia in two thirds, and anemia in half. In HME, the leukocyte abnormalities are primarily lymphopenia and monocytopenia. In HGA, neutropenia is more common, especially with illness of longer duration. Elevations of hepatic transaminases are seen up to 80 percent of the time in both HGA and HME.

A variety of complications may be seen in both infections. These include protracted fever, renal dysfunction occasionally of sufficient severity to require dialysis, acute respiratory distress syndrome, myocarditis, neuropathies and plexopathies, opportunistic infections, and a toxic shock–like syndrome.[50,59,150] Whereas persistent infection is much better documented in reservoir hosts, there has been a case report of fatal, treatment-refractory persistent infection in an older adult, although relapse after doxycycline therapy is thought to be otherwise unheard of.[54] There is one case report of fatal seronegative HME in a patient with advanced human immunodeficiency virus (HIV) infection.[125] Up to half of patients with HME or HGA require hospitalization. The mortality rate is 3 percent for ehrlichiosis and 0.5 percent for anaplasmosis.

Diagnosis. In contrast to RMSF and other infections with agents in the genus *Rickettsia*, anaplasmosis and ehrlichiosis are primarily infections of circulating leukocytes. This potentially allows the diagnosis to be made at the point of care or during the patient's clinical illness. Peripheral blood smear examination will reveal morulae in neutrophils in 25 to 75 percent of patients with HGA;

intramonocytic morulae are seen in 10 percent or less of patients with HME.[6,7,159] Whereas the sensitivity of this examination is low, a positive blood smear is pathognomonic and will allow a real-time diagnosis. PCR amplification of a peripheral blood specimen is a more sensitive alternative for both anaplasmosis and ehrlichiosis; it is also the only modality available for the specific diagnosis of *E. ewingii* infection. Reported sensitivities range from 60 to 85 percent for HME and 67 to 90 percent for HGA.[6,7,84,123] These assays are available from some clinical laboratories. The sensitivity of both blood smear examination and PCR is abrogated by antecedent doxycycline treatment.

Serology by indirect IFA assay remains the most sensitive and widely used means to diagnose ehrlichiosis and anaplasmosis. Paired acute and convalescent sera must be obtained, and a fourfold rise in antibody titer is considered diagnostic. The reported sensitivity is 88 to 90 percent for HME and 82 to 100 percent for HGA.[40,123,181] Antibodies to *Ehrlichia* and *Anaplasma* may be crossreactive, so simultaneous serologic testing for both infections is preferred. The use of paired acute and convalescent sera must be emphasized for two reasons: (1) a single acute serum specimen will yield a positive result in only 3 percent of cases; and (2) a positive titer at a single time point may be due to prior infection, asymptomatic seropositivity, or crossreactivity to other infectious agents.[8,123,181]

Differential Diagnosis. A variety of febrile illnesses can be indistinguishable from ehrlichiosis and anaplasmosis, especially early in infection. The most common symptoms, fever, headache, and malaise, are generic. A careful history, exposure assessment, and physical examination can help limit the differential diagnosis. Differential considerations include but are not limited to viral infections (e.g., enteroviruses, adenoviruses) and bacterial infections (including septic and toxic shock syndromes and focal bacterial infections such as pneumonia that have not yet manifested focally). A number of tropical infectious diseases can have similar clinical presentations and laboratory findings; these include dengue virus infection, typhoid fever, malaria, and leptospirosis.

HME and HGA must be distinguished from other tick-borne diseases, in particular RMSF. Compared with RMSF, these infections are less likely to be accompanied by rash and more often are associated with leukopenia or pancytopenia. The similarity of ehrlichiosis and RMSF is emphasized by two retrospective serosurveys in which approximately 10 percent of specimens from patients lacking the serologic criteria for a diagnosis of RMSF fulfilled diagnostic criteria for ehrlichiosis.[77,149] Other tick-borne illnesses, such as babesiosis, Colorado tick fever, relapsing fever, and tularemia, should be included in the differential diagnosis. In fact, the only major tick-borne infection in North America that is unlikely to be confused for HGA or HME is Lyme disease as high fever and systemic toxicity would be unusual for this infection.

Treatment. The drug of choice for treatment of human ehrlichiosis and anaplasmosis is doxycycline. The recommended dosage is 4 mg/kg/day in two divided doses (maximum adult dose, 100 mg twice daily). Treatment should continue for at least 3 days after defervescence for a total course of 5 to 14 days.[170,197] Because both infections may be severe or fatal, doxycycline treatment should be initiated when the diagnosis is suspected, without regard for the age of the child. Severe cases can require a longer course of treatment. Rifampin is an alternative that can be used in pregnancy and in early childhood, particularly when the index of suspicion for anaplasmosis or ehrlichiosis is low. There is contradictory in vitro evidence about fluoroquinolones, and these are not recommended for the treatment of either infection. Prophylactic treatment after tick bites is discouraged for the prevention of HGA, HME, or other tick-borne rickettsial illnesses.

Coinfection. HGA shares the same tick vector and geographic distribution as *Borrelia burgdorferi* and *Babesia microti*, the agents of Lyme disease and human babesiosis. Simultaneous coinfection with two or even three of these pathogens occasionally occurs and is well described. As Lyme disease is by far the most common of these three, one should consider coinfection in patients who have Lyme disease that is accompanied by atypically high fever, systemic toxicity, uncharacteristic laboratory abnormalities, or poor response to therapy. Doxycycline therapy for anaplasmosis will be active against *B. burgdorferi*, but the duration of therapy may be shorter than that recommended for early Lyme disease (typically 10 to 14 days). Treatment of babesiosis requires either clindamycin with quinine or atovaquone plus azithromycin.

Q FEVER

Historical Aspects. Q fever (the "Q" is for "query") was first described by Edward Derrick as part of an investigation of an apparently infectious febrile illness in 1937.[44] The cause of Q fever was discovered in the late 1930s independently by Burnet and Freeman in Australia and by Cox in the United States. The organism was named *Coxiella burnetii* in honor of two of the discoverers. Infection with *C. burnetii* is worldwide in distribution and is often asymptomatic. When it causes symptoms, the disease is Q fever; it is typically an influenza-like acute illness characterized by fever, headache, fatigue, and myalgias.[172] It can also cause a difficult to diagnose chronic infection, particularly in patients with preexisting valvular heart disease.

The Organism. *C. burnetii* is a small gram-negative coccobacillus that looks like most rickettsiae. However, it has recently been reclassified in the Gammaproteobacteria on the basis of 16s rDNA studies (Order: Legionellales) and is now understood to be relatively closely related to *Legionella pneumophila*.[101,160] *C. burnetii* is an intracellular pathogen that multiplies within phagosomes in the cells it infects, in contrast to the rickettsiae, which can live independently in the cytoplasm or nucleus of infected cells. It is believed that *C. burnetii* is the only intracellular

pathogen that is able to neutralize the acidic, degradative environment of eukaryotic polyphagolysosomes.[81] Its life cycle is distinctive in that it produces endospores that are similar to those seen in some gram-positive organisms.[155] These small cell variants protect the organism in the external environment, where it can survive for long periods.[172]

C. burnetii is also distinctive because it exhibits antigenic phase variation. Phase I variants are associated with mammalian infection and are highly contagious; phase II variants, of reduced virulence, follow propagation and are associated with a chromosomal deletion that results in a partial loss of lipopolysaccharide that makes the organism noninfectious.[141]

Epidemiology and Transmission. Q fever is distinct from human rickettsial infections in that it is primarily a disease of animals that is transmitted to humans by contact with infected animals rather than by an arthropod bite. It infects a broad range of animals including mammals, birds, and arthropods (mostly ticks). The most common sources of human infection are cattle, goats, and sheep, but pets (including dogs, cats, rabbits, and pigeons) can be vectors.[172] *C. burnetii* organisms are found in very high concentration in the placentas of infected parturient animals and are shed into the environment after labor or abortion.[101] Transmission of infection to humans is through aerosols. Unfortunately, the organisms can be wafted by the wind and infect people with no known exposure.[171] Epidemics have occurred in a variety of situations like abattoirs, tanneries, and shearing camps in rural areas. Cases have been reported of schoolchildren who went to farms on field trips.[110] Laboratory outbreaks are also a concern,[75] and the organism should be cultivated only in a biosafety level 3 laboratory.[101]

Outbreaks of Q fever can occur and cause massive public health ramifications. There was, for example, an epidemic of more than 2200 cases in the Netherlands in 2009 that resulted in the prophylactic slaughter of 50,000 dairy goats in an attempt to end the outbreak.[108]

Pregnant women can transmit the infection to their infants, although the risk of abortion with Q fever is considerable. Those infants not aborted are likely to be delivered prematurely or to have low birth weight.[138]

The prevalence of human Q fever is unknown. The diagnosis is difficult to make, and systematic epidemiologic evaluations are few and overreliant on antibody testing in subjects with variable suspicion of disease. The number of reported cases (an average of 50 to 60 cases per year to the CDC) almost certainly substantially underestimates the actual incidence.[31] The disease has been diagnosed in children younger than 3 years and should be considered during an evaluation for fever of unknown origin.[147]

Pathology. Mortality from Q fever is rare, so autopsy specimens are relatively uncommon. Pathologic series obtained during outbreaks described liver and bone marrow disease, in which distinctive fibrin-ring and lipid granulomas were seen. Granulomas have also been seen in the lungs at autopsy. The cellular response was thought to be primarily histiocytic.[158] Biologic control of *C. burnetii* requires a T-cell response, and patients with impaired cellular immunity (cancer patients, HIV-infected people) are at high risk for chronic infection.[101]

Clinical Manifestations. Q fever is manifested in both acute and chronic forms. The most common outcome of *C. burnetii* infection is an asymptomatic seroconversion. Symptomatic Q fever is particularly uncommon in children; infected adults are more likely to be symptomatic than children.[172] Using standard diagnostic criteria, in 2002, Maltezou and Raoult could identify 46 published pediatric cases (many patients previously described did not meet current standards for diagnosis). The most common manifestations in children were fever and pneumonia. Other common manifestations were febrile seizures, meningeal irritation, malaise, lymphadenitis, and anorexia. The fever was typically sustained for 5 to 10 days.[110] Q fever myocarditis has been diagnosed in three pediatric patients.

In adults, acute Q fever is manifested as an influenza-like syndrome with the abrupt onset of high fever, fatigue, headaches, and myalgias. Atypical pneumonias can occur, but the chest radiograph is usually normal and the primary manifestation is a nonproductive cough. Hepatitis is common, although it appears to be regionally distributed (some areas have more pneumonia, some more hepatitis). Maculopapular and purpuric rashes are seen in 10 percent, and myocarditis (although rare) can be potentially fatal.[172]

Chronic Q fever most often occurs in patients with some form of immune compromise. In particular, patients with T-cell defects, pregnant women, and patients with abnormal heart valves are at risk for chronic Q fever. It occurs in 1 to 5 percent of *C. burnetii*–infected patients, symptomatic and not, and may develop months or years after the primary infection.[172] Q fever endocarditis is manifested with low-grade fever, nonspecific cardiac findings, and a positive antibody test response for *C. burnetii*. It occurs primarily in patients with preexisting valvular disease. A 2002 review article found five cases of pediatric Q fever endocarditis, all of which had vegetations on the child's heart valves. The diagnosis is made serologically. *C. burnetii* was demonstrated on the valves from two of the cases. Q fever osteomyelitis has also been rarely seen in normal children.

Q fever can be severe during pregnancy; 33 confirmed cases were investigated, and in only 5 cases was there a normal pregnancy and healthy term delivery.[110] A subsequent study identified 53 pregnant women with Q fever. Eighty-one percent of patients who were not treated with long-term trimethoprim-sulfamethoxazole therapy had complications: 5 had spontaneous abortions, 10 experienced intrauterine fetal deaths, 10 had fetal intrauterine growth retardation, and 10 were delivered prematurely. Patients treated with long-term trimethoprim-sulfamethoxazole therapy were protected from chronic maternal Q fever, placental infections, and obstetric complications.[24]

Diagnosis. *C. burnetii* can be diagnosed by several techniques, but for practical reasons the primary diagnostic modality is serology. The most commonly used test is an

IFA assay. The test is actually directed at detection of antibodies against phase II antigens, the nonpathogenic form of the organism. Antibodies peak 4 to 8 weeks after the onset of disease. Detection of anti–phase I antigens is used in the diagnosis of chronic Q fever (e.g., endocarditis, osteomyelitis) because in chronic Q fever, the level of anti–phase I antibodies will exceed anti–phase II antibodies.[101] Culture of *Coxiella* is possible, but because of the high degree of transmissibility, culture should be undertaken only by reference laboratories with biosafety level 3 facilities. If culture is used, either blood or operative specimens of vegetations are acceptable, although the latter will be more sensitive.[185] PCR is also available from reference laboratories; tests on samples from vegetations will be more sensitive than those from blood. A variety of staining techniques can also be used to demonstrate *C. burnetii* in infected tissues.[101]

Differential Diagnosis. Because Q fever is not common, routinely searching for it seems impractical, but it is almost certainly underdiagnosed. The acute form of Q fever is essentially self-resolving, and antibody titers do not peak for several weeks after the onset of disease, so diagnostic testing is generally unnecessary. In the correct situation, where there are outbreaks (as occurred in the Netherlands), or for individuals with animal exposure or living in rural areas (particularly with heavy sheep, goat, and cattle farming), *C. burnetii* infection should certainly be considered in the differential. Where the diagnosis becomes critical is in patients with classic fever of unknown origin, for which chronic Q fever should be strongly considered. For patients with known valvular disease or immune compromise, including pregnancy, the possibility of Q fever should be evaluated through the use of serologic screening.

Treatment. Because acute Q fever is generally self-resolving, particularly in children, treatment is generally not necessary. The classic therapy for adults is doxycycline, and alternatives include trimethoprim-sulfamethoxazole, fluoroquinolones, and clarithromycin.[110] The important exception in regard to treatment is the situation of valvular heart disease because 39 percent of cases of acute Q fever will result in endocarditis in patients with preexisting valvular disease.[57] In those cases, the acute treatment should include both doxycycline and hydroxychloroquine.

In contrast to acute disease, chronic Q fever requires prolonged treatment. Eighteen to 36 months of both doxycycline and hydroxychloroquine is recommended.[110] Valve replacement may unfortunately be necessary for cure in cases of endocarditis. Pregnant women should be treated throughout pregnancy with trimethoprim-sulfamethoxazole to prevent transmission and abortion or premature delivery.[138]

Prevention. A vaccine for Q fever was developed in Australia for use in people with occupational risks, but it is not available in the United States. Most of the preventive strategies involve minimizing contact with infected animals and post-delivery materials through the rapid and hygienic disposal of placentas and aborted fetuses.[30]

MYCOPLASMA

CHAPTER 195

Mycoplasma and Ureaplasma Infections

James D. Cherry • Natalie M. Quanquin

Mycoplasmas and ureaplasmas, the smallest free-living microorganisms, are ubiquitous in nature. More than 100 species have been recovered from many animals, including human beings.[811,978,1012,1020] Of this group, 17 have been identified as human pathogens or as part of the normal human flora, with *Mycoplasma pneumoniae* causing respiratory disease as well as a protean array of other clinical manifestations and the genital mycoplasmas (*Mycoplasma hominis*, *Mycoplasma genitalium*, *Ureaplasma urealyticum*, and *Ureaplasma parvum*) having clinical significance in neonates and as sexually transmitted infections (STIs).

These organisms lack a cell wall, giving them the class name Mollicutes, which means "soft skin."[438] The genera name *Mycoplasma* is derived from Greek and Latin. *Myco* refers to the mycelial, or filamentous, characteristic, and *plasma* indicates the plasticity and pleomorphism of the organism.[951] *Urea* in *Ureaplasma* indicates the presence of urease,[327] and although this group is in its own genus, because of its shared history it is commonly included as a "mycoplasma" in the literature.

HISTORY

In 1898 Nocard and Roux[743] recovered the first *Mycoplasma* organism from cattle with contagious pleuropneumonia. Shortly after the original discovery, many other mycoplasmas were recovered from several different animals.[397] These other mycoplasmas, which frequently were not associated with disease, originally were called *pleuropneumonia-like organisms;* this designation was abbreviated to PPLO. The term PPLO enjoyed general use until the early 1960s.

The first isolation of a mycoplasma from a human was reported in 1937 by Dienes and Edsall.[234] This organism, now recognized as *M. hominis*, was recovered from an abscessed Bartholin gland. In 1944, Eaton and colleagues[257] reported the recovery of an organism, originally called the Eaton agent, from persons ill with primary atypical pneumonia. For many years, the Eaton agent was considered to be a virus, even though it was inhibited by streptomycin and chlortetracycline.[255,256] In 1961, Marmion and Goodburn[633] noted that the Eaton agent was morphologically similar to PPLOs. In 1962, the organism now known as *M. pneumoniae* was cultivated on a cell-free agar medium and was shown in human volunteer studies to be the etiologic agent of primary atypical pneumonia.[146,150,397]

In 1954, Shepard[879] reported the recovery of PPLOs with a distinctive small-colony characteristic from men with and without nongonococcal urethritis. These T strains (T for tiny), as they were called, now are classified as *Ureaplasma*. Early literature referred to both ureaplasmas as *U. urealyticum;* however, sequencing techniques have shown sufficient differences that they are now recognized as a separate species—*U. parvum* (formerly biovar 1) and *U. urealyticum* (formerly biovar 2).[115,152,154] One center that rescreened respiratory and genital samples sent to them over the previous 10 years found that the majority of mollicutes isolated were *Ureaplasma* spp. and that the majority of those sequenced (67%) were actually *U. parvum*.[875]

The observation in the 1970s that some men with nongonococcal urethritis and negative cultures still responded to tetracycline led to the closer examination of urethral smears and the discovery of small motile spiral forms that resembled the insect and plant pathogens of the genus *Spiroplasma*. In 1981, this new microbe was classified as *M. genitalium*, and with a 580-kb genome, it has been considered the smallest known organism capable of independent growth and reproduction.[956,958,978,981,982] It served as a guide for the minimal requirements needed to create a synthetic genome, achieved by John Craig Venter and his team in 2010.[344]

CLASSIFICATION

Mycoplasma, *Ureaplasma*, and *Acholeplasma* are genera of the family Mycoplasmataceae, in the order Mycoplasmatales, which belongs to the class Mollicutes.[326,811,1008,1012] Both *Mycoplasma* and *Ureaplasma* require cholesterol for growth, have a genome with a molecular weight of approximately 4.5×10^8, and have nicotinamide adenine dinucleotide (NADH) oxidase localized in the cytoplasm. The limited size of their genomes prevents them from encoding many of the enzymes necessary for amino acid synthesis and energy production, making them slow-growing, fastidious organisms that are difficult to isolate in culture. They generate adenosine triphosphate (ATP) through carbohydrate fermentation (glycolysis), lactate oxidation to pyruvate, and/or arginine hydrolysis, depending on the species.[491] Members of the genus *Ureaplasma* are also able to hydrolyze urea.[881,882,955]

The normal human mollicate flora includes 14 *Mycoplasma*, 2 *Ureaplasma*, and 1 *Acholeplasma* spp.* These

TABLE 195-1 **Mollicutes Flora of Humans Listed by Site of Most Common Isolation and Prevalence**

Organism	Prevalence
Respiratory Tract	
Mycoplasma salivarium	Very common
Mycoplasma orale	Very common
Mycoplasma buccale	Rare
Mycoplasma faucium	Rare
Mycoplasma lipophilum	Rare
Mycoplasma pneumoniae	Common
Mycoplasma amphoriforme	Rare
Acholeplasma laidlawii	Rare
Genitourinary Tract	
Mycoplasma hominis	Very common
Mycoplasma genitalium	Rare
Mycoplasma fermentans	Rare
Mycoplasma primatum	Rare
Mycoplasma spermatophilum	Rare
Mycoplasma penetrans	Rare
Ureaplasma urealyticum	Very common
Ureaplasma parvum	Very common
Blood	
Mycoplasma pirum	Rare

Data from References 579, 630, 912, 970, 978, 981, 1016, 1020.

organisms are listed by site of most common isolation and frequency of occurrence in Table 195-1. Most species do not invade submucosal tissues and do not cause disease in immunocompetent hosts unless this protective barrier is breached through surgery or trauma. *Mycoplasma salivarium* and *Mycoplasma orale* are commonly part of the normal respiratory flora and have not been associated with illness in nonimmunocompromised persons. *M. hominis*, *U. urealyticum*, and *U. parvum* also are recovered commonly from human genital tracts, and although they are considered normal flora they can trigger inflammatory processes in pregnant women that have been linked to preterm labor. *M. genitalium* is also found in the genital tracts of sexually active individuals and is a cause of nongonococcal urethritis. Inflammatory processes resulting from the presence of *M. genitalium* and *Mycoplasma fermentens*, another colonizer of the genital tract, are possible; however, a link with adverse pregnancy outcomes has not been established (Tully J G. Personal communication. December 1, 1991).[550,952,1012,1019] Persistent infections in blood, bones, joints, and kidneys with *Mycoplasma penetrans*, *Mycoplasma pirum*, *M. fermentans*, *M. hominis*, and *U. urealyticum* have occurred in patients with immunodeficiencies (Tully J G. Personal communication. December 1, 1991).[55,688] *Mycoplasma buccale*, *Mycoplasma faucium*, *Mycoplasma amphoriforme*, *Mycoplasma primatum*, *Acholeplasma laidlawii*, and *Mycoplasma lipophilum* rarely are isolated and are not thought to cause disease in nonimmunocompromised humans. *M. pneumoniae* is a common cause of respiratory and other human illness.

MYCOPLASMA PNEUMONIAE

Properties

Morphology

Because mycoplasmas lack a cell wall, they all tend to be pleomorphic. Kammer and colleagues[480] studied the morphologic characteristics of *M. pneumoniae* organisms grown in broth medium by scanning electron microscopy and grouped their observations by days of incubation. From 0.3 to 2 days, the predominant morphologic feature consisted of 0.51 ± 0.011-μm symmetric round forms in tightly packed clusters. During the interval from day 2 to day 6, branched and straight filaments and bulbs were the predominant forms. The bulbous elements had a diameter of 0.25 ± 0.006 μm, and the filamentous forms were 0.19 ± 0.005 μm in diameter. The filaments were intertwined, and occasional round forms were observed. From day 6 to day 10, the organisms had a rounded shape but were asymmetric. Their diameter was 0.72 ± 0.027 μm, and they occurred in groups of three or four cells. Biberfeld and Biberfeld[71] noted that *M. pneumoniae* filamentous forms varied in length from 1 to 5 μm.

The ultrastructure of *M. pneumoniae*, as well as that of all members of the family Mycoplasmataceae, is relatively simple and consists of a cell membrane and cytoplasm.[327,977] In 7-day *M. pneumoniae* cultures, Domermuth and associates[237] noted the following characteristics: elementary bodies 105 to 120 nm in diameter, mature cells with a maximal diameter of 690 to 750 nm and an average diameter of 440 to 590 nm, asymmetry of the limiting membrane, electron-dense lines outside the limiting membrane, and dense bodies as cytoplasmic inclusions.

Wilson and Collier[1048] studied the ultrastructure of *M. pneumoniae* in hamster tracheal organ culture and noted filamentous organisms with three-layered membranes; the cells were polymorphic, but each had a specialized terminal structure at the site of attachment to the organ culture. This terminal structure had a dense central core containing a denser central filament. Between the organism and the organ culture cell, fusion was not detected, but a loose network of fibrils was noted between the two surfaces. The bodies of the mycoplasmas contained densely staining fibrillar material and cytoplasmic granules, both of which contained nucleic acid.

Motility and Multiplication

Bredt[101] studied *M. pneumoniae* motility and multiplication on a glass surface in liquid medium by phase-contrast microscopy. The organisms were observed to multiply by binary fission; first, short filamentous structures were formed, which then separated into two cells. A growth cycle between two separations lasted approximately 3 hours. After division, the new cells moved by means of a gliding motion. The gliding speed has been noted to be approximately 0.2 to 0.5 μm/sec, but maximal speeds of 1.5 to 2.0 μm/sec have been observed.[804]

Composition

Mycoplasmas are composed of approximately 40 to 60 percent protein, 10 to 20 percent lipid, and a variable amount of carbohydrate. The *M. pneumoniae* genome is circular, double-stranded DNA with a contour length of 4.8×10^8 D and a size of 816 kb.[695] The guanosine plus cytosine content of the DNA is 38.6 to 40.8 percent.[93,729,811,954]

Growth Characteristics and Physical Properties[145]

M. pneumoniae grows in *Mycoplasma* broth medium and on agar enriched with yeast extract and animal serum. *M. pneumoniae* ferments carbohydrates and requires sterol for growth. It grows under both anaerobic and aerobic conditions, but growth is more consistent when it is incubated in nitrogen and 5 percent carbon dioxide. When compared with other mycoplasmas isolated from humans, *M. pneumoniae* grows relatively slowly, with visible formation of colonies rarely occurring in less than 1 week and possibly taking 3 weeks or more. Repeated agar passage results in more rapid growth, and laboratory strains thus treated produce colonies in 3 days.

M. pneumoniae colonies on agar generally appear different from the classic *Mycoplasma* "fried egg" look noted with other types recovered from humans. The *M. pneumoniae* colony is spherical and dense, with a rough ("mulberry") surface.

M. pneumoniae has the following enzyme systems: $NADH_2$ oxidase, nicotinamide adenine dinucleotide phosphate ($NADPH_2$) oxidase, lactate dehydrogenase, probably succinic dehydrogenase, and diaphorases.[397] In liquid medium the following can be noted: acid color change in medium with added glucose and phenol red as a result of glucose metabolism, reduction of methylene blue in medium as a result of dehydrogenase activity, and reduction of 2-3-5 tetrazolium chloride to red formazan by dehydrogenase activity.[951]

On agar, *M. pneumoniae* hemolyzes erythrocytes in an agar overlay by liberation of peroxide. Erythrocytes and other cells adsorb to *M. pneumoniae* colonies, and organisms in suspension cause hemagglutination. *M. pneumoniae* has also been found to create biolfims on abiotic surfaces,[524] which may help it survive in the environment.

Mycoplasmas, including *M. pneumoniae*, are heat sensitive. They have a half-life of less than 2 minutes at 50° C (122° F) and lose viability within 1 week at room temperature.[977] They can be stored for several years at –20° C (–4°F), but –70° C (–94° F) is optimal for long-term storage.

Mycoplasmas are resistant to osmotic environmental changes but are sensitive to detergents. They are inhibited by gold salts and antibiotics not directed against cell wall synthesis.

Antigenic Composition

The following immunologic reactions have been noted in association with *M. pneumoniae*–host serum interactions: specific complement fixation; precipitation in gel; growth inhibition; indirect hemagglutination; metabolic inhibition; antigen-antibody union identified by immunofluorescence, enzyme-linked immunosorbent assay (ELISA), and radioimmunoassay; adherence inhibition assay; and nonspecific complement fixation (i.e., positive serologic test result for syphilis) and agglutination (i.e., cold and *Streptococcus* MG agglutinins).* *M. pneumoniae* organisms have both membrane and cytoplasmic antigens.[291,497] Two membrane antigens can be identified by immunodiffusion,[789] with the major membrane antigen being found in the lipid fraction of the organism.[497] The antigens are glycolipids and are of major importance in complement fixation, metabolic inhibition, and mycoplasmacidal reactions.[125] The cytoplasmic (soluble) antigen, which also contains lipid, can be identified by complement fixation when the antigen is prepared by phenol extraction. Many surface lipoproteins are also differentially expressed on contact with epithelial cells[385] and are thought to play a role in both activating and evading the innate immune system.[109,439]

Humans have an immunoglobulin (Ig)G immune response to seven principal protein antigens.† These seven polypeptides have the following molecular masses: 170, 130, 90, 68, 45, 35, and 30 kDa. The 170-kDa antigen is the P1 protein. This protein is localized at the surface of the terminal organelle (terminal structure), is the major adhesin responsible for attachment, and is the cause of the gliding motility of the organism. Antibodies to P1 protein inhibit hemadsorption and adherence to respiratory epithelium.‡ Another important adhesin is the 30-kDa protein (P30 adhesin). In addition to the P1 and P30 proteins, multiple accessory proteins are involved in the adherence of *M. pneumoniae* to host cells,[810] including P65, HMW1, HMW2, HMW3, and A, B, and C.[46,393]

The 68-kDa community-acquired respiratory distress syndrome (CARDS) toxin is a recently identified protein unique to *M. pneumoniae* but that shares some homology with pertussis toxin.[482,662] It possesses adenosine diphosphate (ADP) ribosyltransferase (ART) activity, is highly immunogenic, and has been associated with airway cellular damage.[662] Diagnostic assays based on this protein have recently been developed.[702]

M. pneumoniae strains can be divided into two types on the basis of the sequence variation in the P1 gene.[242,243,251] Five subtypes of the type 1 strain and three subtypes of the type 2 strain have been noted by restriction fragment length polymorphism (RFLP).

Membrane determinants of *M. pneumoniae* cross react with the erythrocyte glycoprotein containing the I antigen and the related sugar chain (F1)[404,454]; with pneumococcal serotypes 23 and 32[17]; with the glycolipids of spinach, parsnips, and carrots; with selected strains of *Staphylococcus aureus* and group A streptococci; and perhaps with the filamentous hemagglutinin of *Bordetella pertussis*.[369,446,498,999]

Animal Susceptibility

M. pneumoniae grows and causes pneumonia in hamsters and cotton rats and causes inapparent infection of the bronchial epithelium of chicken embryos.[798]

Epidemiology

Epidemic Pattern

In large urban areas, *M. pneumoniae* is endemic; infection and disease occur throughout the year. Foy and associates[309,314] noted cultural or serologic evidence of *M. pneumoniae* infection in a Seattle, Washington prepaid medical care group during all seasons throughout an 11-year period. Similar endemicity has been reported in other studies.[686,692,742] Wan and colleagues[1023] tested air filters at a hospital in Taiwan and detected seasonal peaks of *M. pneumoniae* in the pediatric emergency department (July) and outpatient areas (August to January). In addition to the background endemic pattern, *M. pneumoniae* enjoys a cyclic epidemic pattern that is specific for a particular urban community. Epidemics have occurred at 3- to 7-year intervals,[276,314,475,582,742] most recently in Europe and Jerusalem from 2010 to 2012.[141,261,569,738,986] Epidemics, which develop slowly, usually start in the fall and persist in the community for 12 to 30 months.

As part of an influenza surveillance program, Layani-Milon and associates[555] studied acute respiratory infections in outpatients for six winters in the Rhône-Alpes region of France by polymerase chain reaction (PCR) plus a hybridization-based detection system. Each year from 1992 to 1997, at least one peak of *M. pneumoniae* infection was noted in the late fall. Overall, they studied 3897 children and adults with acute respiratory illnesses, and 7.3 percent were found to be infected with *M. pneumoniae*. The yearly rate of *M. pneumoniae* cases fell from 10.1 percent in 1992 to 1993 to 2.0 percent in 1995 to 1996; in the subsequent year (1996 to 1997), it rose to 4.2 percent.

Incidence of Infection and Disease

In the past, most pediatricians and other physicians considered *M. pneumoniae* illness to be uncommon in the general population. The initial epidemiologic studies were concerned mainly with the occurrence of pneumonia in closed populations such as the military and boarding schools.* During the past 49 years, however, many large studies in civilian populations, coupled with more sensitive diagnostic techniques, have indicated that both infection and disease with *M. pneumoniae* occur commonly.†

Hornsleth[418] examined 367 serum samples collected from children hospitalized in Copenhagen from September 1963 to May 1965 for complement-fixing antibodies. He noted that 42 percent of infants 6 to 11 months of age had demonstrable antibody; from 1 to 9 years of age, more than two thirds of the children had antibody. Suhs and Feldman[936] found a similar high prevalence of hemagglutination-inhibiting antibody in the sera of residents of Point Barrow, Alaska, but only 5 percent of the serum samples from a children's home in Syracuse had measurable antibody. A study of 319 pediatric patients with chronic respiratory disease found that 32.6 percent had bronchoalveolar lavage fluid positive for mycoplasmas, of which only 31 percent represented *M. pneumonia*.[778] Brunner and associates[114] detected serum antibody by the sensitive radioimmunoprecipitation test in 28 percent of 7- to 12-month-old infants, 55 percent of 13- to 24-month-old children, 67 percent of 25- to 60-month-old children, and 97 percent of persons older than 17 years. The high antibody prevalence noted in this study, as well as the findings in Copenhagen and Alaska, suggests an infection incidence rate of approximately 20 to 30 percent per year in a susceptible population of young children. The prevalent antibody noted at an early age in these studies possibly is not caused specifically by *M. pneumoniae* infection but instead could be the result of exposure to the many cross-reacting antigens in nature.[17,342,498] However, studies by Fernald and colleagues,[294] in which infants and children in a daycare center were monitored systematically, indicated a yearly infection rate of approximately 12 percent.

Monto and colleagues,[692] in a large study involving 3243 persons, investigated the incidence of infection in six yearly cohort groups of children and adults. Infection was determined by significant rises in titer of complement-fixing antibody on three serum specimens collected during a 1-year period from each subject. The overall yearly infection rate was found to be 5.3 percent. The highest rate (8.8%) occurred in the 5- to 9-year-old group. Infants younger than 1 year had a rate of 2.8 percent.

Brunner and associates[114] noted that geometric mean antibody titers tended to increase with increasing age, which suggested that the older children were being reinfected. Fernald and colleagues[294] reported that 5/22 children infected with *M. pneumoniae* in their investigation experienced reinfections during the 5-year observation period. In the study by Monto and associates,[692] 24.4 percent of the 172 infections detected in subjects of all ages were re-infections. During a 12-year serologic surveillance period, Foy and coworkers[314] noted great variation in the incidence of *M. pneumoniae* infection; in the period from October 1965 to May 1966, only 0.2 percent of 398 children had fourfold rises in complement-fixation antibody titer, whereas during the May 1973 to May 1974 period, 35 percent of 246 subjects 10 to 20 years of age had serologic evidence of infection.

The incidence of disease caused by *M. pneumoniae* depends on the endemic or epidemic prevalence of the organism in the community and is age related. The incidence of *M. pneumoniae* by age for two epidemics and the surrounding endemic periods in Seattle was studied by Foy and associates.[314] The highest epidemic attack rate was 14/1000 children 5 to 9 years of age, and the highest endemic attack rate (4/1000) occurred in the same age group. Children 10 to 14 years of age had the second highest attack rate during both epidemic and endemic

*References 149, 686, 838, 928, 930, 993.
†References 39, 40, 73, 114, 130, 200, 231, 239, 248, 264, 272, 294, 307, 311-314, 316, 318, 353, 356, 367, 418, 457, 466, 475, 582, 591, 597, 671, 691, 692, 736, 742, 766, 878, 936, 976.

periods. The attack rate in children younger than 5 years was about twice that observed in young adults.

The ratio of symptomatic to asymptomatic infection has varied across studies. In family studies, both Balassanian and Robbins[45] and Foy and associates[307] noted that only 15 percent of infections were asymptomatic, whereas Saliba and associates[838] noted that 55 percent of the residents of a boys' home had asymptomatic infection. Chanock and colleagues[149] observed that only 1/30 infections in Marine recruits manifested as clinically apparent pneumonia.

Incubation Period

The reported incubation period has varied from a mean of approximately 1 week in volunteer studies and point-source epidemics to 3 weeks in community outbreaks.* In a volunteer study, Rifkind and colleagues[816] administered tissue culture–grown *M. pneumoniae* in a concentration of 320 to 1280 EID_{50} (mean egg-infective dose) into the nose and posterior pharyngeal area of 27 men with no demonstrable antibody. In this study, pneumonia occurred 9 to 12 days after inoculation, following 1 to 3 days of upper respiratory tract illness. In six volunteers, only upper respiratory tract illness was noted, and the incubation period varied from 4 to 9 days. In a similar study in which volunteers received 10^6 to 10^7 broth-grown organisms, the incubation period was 8 to 10 days.[900]

In an interesting common-source outbreak caused by an intense 8-hour exposure at a party, the peak incubation period was 13 days and most of the cases occurred between days 11 and 14.[278] In another probable point-source outbreak, which may have resulted from a room aerosol, the incubation period varied from 4 to 9 days.[846] In studies of case-to-case intervals in families, Foy and associates[307] reported a median incubation time of 23 days, with most of the cases occurring between days 16 and 25. In similar studies, Copps and colleagues[200] noted an average interval of 21 days, and Biberfeld and Sterner[73] found a modal value of 20 days. A point-source outbreak in a family unit was described in which all seven family members became ill 10 to 16 days after the onset of symptoms in the index case.[503]

The longer incubation period in the family situation than in the volunteer studies and the point-source outbreaks may be the result of larger inocula in the last instances. In contrast to other respiratory illnesses such as measles and influenza, the spread of disease caused by *M. pneumoniae* in both closed populations, such as military training units and boarding schools, and open communities is usually slow. For example, the introduction of influenza or measles into a family most often results in infection of all susceptible persons from the primary case. In contrast, the spread of *M. pneumoniae* through a family of six people probably would require three or four passages. Foy and associates[307] noted secondary attack rates in families of 64 percent for children and 17 percent for adults. Biberfeld and Sterner[73] reported secondary infection rates of 41 and 84 percent, respectively, for adults and children in families. In contrast to family groups, the spread of *M. pneumoniae* in schools and other situations of brief exposure is low.[311,317] In one Seattle elementary school, the infection rate was 18 percent. Foy and Alexander[309] believe that neighborhood spread among playmates is more important than school exposure in community transmission of *M. pneumoniae*.

Transmission in families occurs during the acute phase of illness, and transmission by persons with asymptomatic infection has not been documented.[311]

Geography

The endemic and epidemic presence of *M. pneumoniae* has been demonstrated in the urban areas of developed countries with temperate climates throughout the world.* Serologic investigations in more remote areas, including both arctic and tropical zones, also indicate the presence of *M. pneumoniae* infection. Suhs and Feldman[936] found measurable antibody in the serum of 68 percent of 169 persons in Point Barrow, and Golubjatnikov and associates,[356] in a study of children in a remote Mexican highland community, detected seropositivity in 16 percent of 637 children. Serologic evidence of infection also has been noted in Cairo, Singapore, Hong Kong, the West Indies, and southern Africa.[144,475] Incidence studies have not been performed in rural areas, but patterns of infection probably would be characterized by epidemic periods of a year or so and then complete absence of *M. pneumoniae* circulation for several years.

Sex

Although the results of studies have varied, the difference in the incidence of *M. pneumoniae* disease by sex is small. During the 11 years of study in Seattle, Foy and associates[314] noted that the rate of *M. pneumoniae* pneumonia was higher in women than in men in the 30- to 39-year age group (1.8 vs. 1.2/1000); in infants, boys were afflicted more often than girls, but otherwise the rates for children by sex were virtually identical. Jensen and associates[466] found that pneumonia, otitis media, and nasopharyngitis in various combinations occurred more commonly in boys than in girls. Monto and colleagues[692] noted that boys younger than 5 years of age had more infections, but that the reverse was true for children 5 to 14 years of age. In a review of Japan's National Surveillance Data, Eshima and colleagues[271] found a slightly greater female preponderance in symptomatic infection at all ages except those over 70 years old. In other studies involving all age groups, males have shown a slightly greater frequency of illness than females.[632,742] In the Seattle family studies, symptoms were more severe in boys than in girls.

Pathogenesis and Pathology

Sequence of Events in Infection

M. pneumoniae infection is acquired via the respiratory route from the respiratory secretions of an ill person infected with this agent. Spread can be accomplished by

*References 73, 200, 278, 307, 311, 315, 816, 846, 901, 978.

*References 73, 231, 286, 311, 314, 457, 582, 612, 632, 716, 742, 921.

small-particle aerosols or large droplets of secretions coming in contact with the epithelial surface of the nasopharynx and perhaps the surfaces of the lower respiratory tract (i.e., trachea, bronchi, and bronchioles), as well. In volunteer studies, Couch[205] observed that the 50 percent human infectious dose by small-particle aerosol was 1 colony-forming unit (nasal instillation required a dose that was 100 times greater).

Because epidemiologic data indicate the need for close and perhaps prolonged personal contact for transmission of infection, transmission by small-particle aerosol probably occurs rarely under natural conditions. After acquisition of the infectious agent, multiplication occurs extracellularly on mucous membrane surfaces. The incubation period, which varies from 4 days to more than 3 weeks, probably depends strongly on the size of the original inoculum. The extent of the respiratory infection increases during the incubation period, and shedding of organisms in respiratory secretions can be observed 2 to 8 days before clinical illness.[205] Initial symptoms of infection include headache, malaise, fever, sore throat, and cough; evidence of lower respiratory tract disease is present within the succeeding 3 days.[231,816] The method of extension of infection within the respiratory tract is unknown. The extent of disease possibly depends totally on the initial distribution of the infectious agent at the time of acquisition rather than on spread of infection from a primary upper respiratory site.

After the onset of clinical symptoms, the concentration of *M. pneumoniae* in respiratory secretions peaks, remains high for approximately 1 week, and then persists for 4 to 6 weeks or longer.[205,231] The associated symptoms and signs in disease caused by *M. pneumoniae* (i.e., meningitis, arthritis, hemolytic anemia, rash, and pericarditis) suggest the possibility of frequent dissemination of the organism from the respiratory tract. Some reviews on the subject tend to discount the possibility of generalized *M. pneumoniae* infection and attribute the associated systemic clinical findings to immunologic events related to respiratory infection.[205,231] However, little published evidence indicates that the organism has been sought carefully in the blood and other sites of dissemination. In many instances *M. pneumoniae* has been recovered from or identified by PCR in the blood, pericardial fluid, middle ear fluid, vesicular skin lesions, pleural fluid, kidneys, brain, and cerebrospinal fluid (CSF).* In addition, the observation of low cerebrospinal fluid glucose in *M. pneumoniae* meningoencephalitis suggests direct involvement by the organism.[515]

Pathology

Pathologic findings in *M. pneumoniae* disease in children have not been reported, and only minimal data from adults are available. However, a reasonable understanding of the pathologic process of *M. pneumoniae* disease can be constructed from studies in the hamster, various tracheal organ cultures, and human biopsy and postmortem material.† The primary damage in *M. pneumoniae* infection is to the epithelial lining of the mucosal surfaces of the respiratory tract. This damage has been observed on the surface of bronchi, bronchioles, and alveoli, and clinical symptoms in children suggest that similar pathologic changes occur in the trachea and upper respiratory tract, as well. Specifically conspicuous is destruction of the ciliated epithelium of the bronchi and bronchioles. Because of mucosal desquamation and ulceration, the lumina contain considerable debris; added to this debris is an inflammatory exudate consisting of fibrin, mononuclear cells, and neutrophils. The alveolar spaces contain similar exudate and edema fluid.

The walls of the bronchi and bronchioles are thickened by edema and contain an infiltrate of macrophages, lymphocytes, and plasma cells. The alveolar walls are also thickened and contain lymphocytes, mononuclear cells, and erythrocytes. Dilation of the septal capillaries occurs. Edema and cellular infiltration extend into the interstitial spaces. Gross examination of the lungs reveals areas of hemorrhage and congestion. The pleura may contain patches of fibrinous exudate, and pleural fluid may be present. The pneumonic areas may be discrete or widespread.

A biopsy specimen of a vesiculopustular skin lesion revealed an epidermis with mild acanthosis and marked edema that primarily was intracellular.[962] The papillary and upper reticular dermis contained neutrophils and round cells, and hemorrhagic foci were present within the upper corium and epidermis. The blister fluid contained plasma protein and neutrophils. Findings in other organs include mesenteric lymphadenitis, focal hepatic necrosis, follicular splenitis, acute myocarditis, and hemorrhagic encephalitis.

Immunologic Events

Specific Antibody. A specific serum antibody response usually occurs after infection with *M. pneumoniae*, and it can be measured by many different serologic techniques: immunofluorescence, complement fixation, indirect hemagglutination, precipitation, growth inhibition, mycoplasmacidal antibody test, ELISA, radioimmunoassay, adherence inhibition assay, and radioimmunoprecipitation test.*

Complement-fixing antibodies occur early in *M. pneumoniae* disease, reach a peak titer in approximately 1 month, and then decline slowly over a variable period. Fluorescent-staining antibodies and antibody determined by ELISA have temporal patterns similar to those of complement-fixing antibodies. Growth-inhibiting antibodies appear later (i.e., 2 to 3 weeks after the onset of illness), peak later, and persist longer than do complement-fixing antibodies. The initial serum immune response includes specific IgM, IgG, and IgA antibodies. After clinical illness and convalescence, specific antibody is located mainly in the IgG serum fraction. Occasionally, significant levels of IgM antibody persist for several months or years after infection.[70,115,267,472] Antibody titer responses in infected children are generally of a lesser

*References 2, 56, 63, 80, 226, 303, 434, 484, 519, 553, 600, 711, 712, 725, 726, 725, 726, 811, 907, 909, 941, 973.

†References 241, 434, 476, 519, 553, 600, 616, 673, 774, 962, 1072.

*References 111, 114, 119, 247, 293, 398, 428, 449, 579, 590, 798, 862, 959.

magnitude than those in adults.[248] Asymptomatic infections in children may not be associated with a measurable serum antibody response. *M. pneumoniae*–specific IgE antibodies have been detected in the sera of patients with asthma, atopic dermatitis, or both conditions.[972]

After infection, specific antibody is also present in nasal secretions and sputum.[69,113] In volunteer studies, Brunner and colleagues[113] noted that 42 and 73 percent of subjects had IgA nasal and sputum responses, respectively. Biberfeld and Sterner[74] found specific antibody in 44/55 sputum specimens from patients with *M. pneumoniae* infection of the lower respiratory tract. They noted IgA antibody in all specimens tested, IgG antibody in 24/31 specimens, and IgM antibody in 13/27 specimens.

Specific Cell-Mediated Immunity. Fernald and coworkers[289,290,291] demonstrated that lymphocytes from adults previously infected with *M. pneumoniae* undergo blast transformation when cultured in vitro in the presence of *M. pneumoniae* organisms. In age-related studies, researchers noted that only one of nine children younger than 4 years of age with documented previous infection had evidence of specific cell-mediated immunity as measured by lymphocyte stimulation.[294] In contrast, 7/12 children older than 4 years and 87 percent of an adult group demonstrated specific lymphocyte stimulation. This study suggests that specific cell-mediated immunity increases as a function of age and depends on repeated infection. Koh and colleagues[517] noted high levels of interleukin (IL)-4 and a high IL-4/interferon (IFN)-γ ratio in the bronchoalveolar lavage fluid of children with *M. pneumoniae* pneumonia, thus suggesting a predominant T_H2-like cytokine response.

Martin and colleagues[635] found that leukocytes from volunteers with *M. pneumoniae* infection demonstrated chemotaxis in the presence of the organism, whereas leukocytes collected before infection did not. Patients infected with *M. pneumoniae* also respond with IFN-γ in their blood and nasopharyngeal secretions early in infection and with IFN-γ during convalescence.[717,718]

Nonspecific Responses. Antibodies to several diverse antigens develop during human infection with *M. pneumoniae*. The best known of these antibodies are cold agglutinins, and they are useful in the diagnosis of *M. pneumoniae* pneumonia.[203,284,398,457,902] Cold agglutinins are directed against the I antigen of erythrocytes.[454,583,902] Most pneumonias in which serum cold agglutinins are noted are caused by *M. pneumoniae*. Cold agglutinins are detected in the serum of approximately 75 percent of patients with *M. pneumoniae* pneumonia; they are less common in *M. pneumoniae* infection without pneumonia.[145]

Patients with *M. pneumoniae* also frequently develop antibodies to the MG strain of nonhemolytic streptococci[581] and occasionally to *M. genitalium*,[585] *M. hominis*,[849] *M. salivarium*, *Mycoplasma hyorhinis*, *Mycoplasma orale*, *Mycoplasma pulmonis*, and *Mycoplasma mycoides* variety mycoides, the etiologic agent of contagious pleuropneumonia of cattle.[568] Cross-reacting antibodies to filamentous hemagglutinin and pertactin of *B. pertussis* also occur.[999] Other heterologous antibodies found in the serum of patients with *M. pneumoniae* infection include those to smooth muscle, the mitotic spindle apparatus, brain, lung, liver, and Wasserman (WR) cardiolipin antigen.[69,75,584] In addition to these findings, Biberfeld and Norberg[72] detected immune complexes by the platelet aggregation technique in the sera of 16/39 patients with acute respiratory illness caused by *M. pneumoniae*. Mizutani[682] demonstrated the presence of circulating immune complexes in most patients with pneumonia caused by *M. pneumoniae*. The same investigator also detected rheumatoid factor in the sera of patients with *M. pneumoniae* disease.[683]

Possible Mechanisms of Disease Production

Numerous studies have been performed in an attempt to understand the pathogenesis of respiratory disease caused by mycoplasmas.* Of particular interest in human *M. pneumoniae* infection is the apparent high prevalence of infection in infants, children, adolescents, and young adults, but the frequently mild nature of disease in infants and young children in comparison with older patients. Some studies suggest that the more severe disease in older patients is associated with reinfection and is mediated somewhat by immunologic responses.

Organ culture and animal studies indicate that damage at the site of primary infection—the respiratory epithelium—is the result of close organism–cell attachment.† This attachment of organism to cell uses neuraminic acid receptors on the cell.[908] In an organ culture system with *M. mycoides* variety capri, ciliary damage was decreased when the cellular receptor sites were treated with receptor-destroying enzyme.[162] Lipman and associates[587,588] noted that one attenuated *M. pneumoniae* strain had lost its ability to cytadsorb. The close association of organism and cell allows the transport of specific damaging material to the cell. Although the precise nature of this substance is not known, the data available suggest that it might be hydrogen peroxide. It is liberated by *M. pneumoniae* in vitro; in organ culture studies, hydrogen peroxide has been shown to be the damaging factor in another *Mycoplasma* infection.[166,588,589] In cell culture, *M. pneumoniae* inhibits host–cell catalase activity.[19] This inhibition of catalase activity enhances the toxicity of the hydrogen peroxide generated by the microorganism. *M. pneumoniae* also enters host cells and persists intracellularly for at least 7 days.[53]

Damage to ciliated respiratory epithelial cells also could be caused by CARDS toxin.[482,662] Another possible important component of *M. pneumoniae* pathogenicity is the induction of proinflammatory and other cytokines during infection.[1057]

In addition to direct damage from inflammatory cytokines and bacterial cytotoxins, additional mechanisms have been proposed in the development of extrapulmonary findings in *M. pneumoniae* infection.[722,1009] Autoantibodies are often detected in these cases, most likely as a result of cross reactivity between host cell proteins and

*References 114, 162-164, 166, 185-187, 193, 195-198.
†References 166, 196, 198, 424, 587, 588, 708, 795, 985.

Mycoplasma membrane antigens. Autoimmune mechanisms have been linked to findings as varied as arthritis, coagulopathies, and encephalitis in *M. pneumoniae* infection. Another mechanism of pathology commonly seen is vascular occlusion, caused by either direct inflammation of the vessels or various coagulopathies associated with *M. pneumoniae* infection. This led to associated findings such as stroke, pulmonary emboli, and coronary artery disease. Although not directly proved, the ability of *Mycoplasma* to bind to erythrocytes and disseminate through the bloodstream may contribute to the high frequency of extrapulmonary findings seen with these infections.[730]

Fernald and associates[292] noted that specific cell-mediated immunity to *M. pneumoniae* as measured by lymphocyte transformation becomes more prevalent with increasing age, as does specific antibody. Their studies suggest that more than one exposure to antigen may be necessary to elicit both humoral and cellular responses. Fernald and Glezen,[292] in an inactivated *M. pneumoniae* vaccine trial in children, noted that lymphocyte sensitivity developed in many recipients but not a humoral antibody response. In a trial of an inactivated vaccine in adults, Smith and associates[900] found that on challenge infection, an exaggerated illness occurred in vaccinees who failed to form humoral antibodies after immunization. These findings have led to the consideration that persistent specific cell-mediated responsiveness might contribute to the pulmonary process in *M. pneumoniae* infection. However, the incubation period of illness in adults and children is similar, which argues against the sensitization theory.[182]

Foy and associates[311] noted that complement-fixing antibodies remained elevated for 2 to 9 years after infection with pneumonia but fell quickly after the second year in persons with mild illness. Protection against reinfection was better in those who previously had pneumonia than in those with mild symptoms.

Clinical Manifestations

Pneumonia

Pneumonia is the most important clinical manifestation of *M. pneumoniae* infection, and this agent is responsible for 10 to 20 percent of all cases of pneumonia.* The highest incidence of pneumonia caused by *M. pneumoniae* in Seattle occurred in children 5 to 14 years of age.[314] In a study in Chiba Prefecture, Japan, researchers noted that the peak age of lower respiratory tract illness caused by *M. pneumoniae* was 4 years.[713] In a prospective study of community-acquired pneumonia in Finland, 11 percent of the children with *M. pneumoniae* infection were younger than 5 years of age, 32 percent were between 5 and 9 years of age, and 57 percent were 10 to 14 years of age.[402] Although researchers frequently state that *M. pneumoniae* pneumonia rarely occurs in children younger than 5 years of age, in actuality, the incidence in this group was found to be about twice that noted in young adults in Seattle.[314]

*References 189, 231, 317, 318, 324, 402, 421, 591, 755, 229, 657, 672, 736, 766, 976, 1063, 1064.

Pneumonia caused by *M. pneumoniae* occurs less commonly in children younger than 2 years of age and rarely in infants younger than 6 months of age. The apparent frequency of *M. pneumoniae* pneumonia is influenced by the relative occurrence of pneumonia caused by other pathogens. During the child's first 5 years of life, *M. pneumoniae* is only one of many agents (e.g., respiratory syncytial virus, adenoviruses, parainfluenza viruses, influenza viruses, *Streptococcus pneumoniae*, and *Haemophilus influenzae*) that cause pneumonia. During later childhood and adolescence, pneumonia as a consequence of infection with these other agents is a rare event; therefore *M. pneumoniae* is the leading cause of pneumonia in these persons.

Because isolation rates of *M. pneumoniae* during both endemic and epidemic periods do not vary greatly by season, as do those of common respiratory viruses, the proportion of patients with *M. pneumoniae* pneumonia increases during the summer months.

Symptoms and Signs. Since 1961, a large number of studies have reported the frequency of signs and symptoms in *M. pneumoniae* infection.* Unfortunately, many studies have included only special populations such as the military and, with few exceptions, community investigations have failed to indicate differences by age. In only a handful of investigations have data regarding children been itemized separately.[107,229,320,931,1064] Table 195-2 presents the relative frequency of symptoms and signs as compiled from eight studies in which both children and adults were included. The hallmark of pneumonia caused by *M. pneumoniae* is fever and cough. The onset of illness usually cannot be demarcated clearly, but malaise, fever, and headache are early complaints. Cough has an onset 3 to 5 days after the beginning of illness and is initially nonproductive. Foy and colleagues[317] and Biberfeld and coworkers[77] noted that 77 and 100 percent, respectively, of the patients that they studied had maximal temperatures greater than 38.9° C (102° F). Copps and associates[200] found that 58 percent of the group that they evaluated had temperatures higher than 39.4° C (103° F) and 4 percent had temperatures higher than 40.6° C (105° F).

The reporting of headache in association with *M. pneumoniae* pneumonia has varied considerably. Nakao and associates[716] noted this report in only 8 percent of subjects, whereas Biberfeld and associates[77] and Foy and colleagues[317] reported it in two thirds of those studied. Chills and the production of sputum are present in about 50 percent of ill patients. Again, great differences among investigations are noted, and they probably are related to the relative ages of the patients.

Coryza is unusual in *M. pneumoniae* pneumonia; therefore, its occurrence should suggest another etiologic agent for illness in a specific patient. In a study involving

children exclusively, Stevens and colleagues[931] noted that coryza occurred more commonly in young children; as might be expected, they found productive cough more frequently in their older patients. Hoarseness, earache, sore throat, gastrointestinal complaints, and chest pain occur in approximately 25 percent of patients.

On physical examination, approximately 75 percent of patients have auscultatory evidence of pneumonia and about half have pharyngitis. Remarkable lymphadenopathy, particularly with cervical involvement, is noted in approximately 25 percent of patients. Twenty-one percent of the patients studied by Foy and associates[317] had otitis media. In other studies, this manifestation was noted in about 5 to 10 percent of cases. Conjunctivitis was reported in almost half the patients reported by Fransen and associates.[323] In contrast, except for Jansson and colleagues,[458] who noted conjunctivitis in 3 percent of their study group, this finding was not mentioned in the other reports. Similarly, rash was reported in 6, 11, and 17 percent, respectively, in studies in Minnesota, Wisconsin, and Seattle,[200,318,625] but it was not mentioned in the other studies.

The most common finding on chest auscultation is dry rales, but musical rales with expiration are noted occasionally. Rales usually persist for 2 weeks, and hearing them a month or more after the onset of disease is not unusual. Occasionally, patients have no auscultatory evidence of pulmonary disease throughout their illness, in spite of the presence of abnormalities on chest radiographs. During illness, cough becomes increasingly prominent; initially it is nonproductive, but later it may produce a frothy white sputum in older children and adolescents. The sputum also may appear purulent and contain blood. Cough persists for 3 to 4 weeks and longer after nonrespiratory symptoms such as fever and headache have subsided.

In a study of 44 children with lower respiratory tract illness caused by *M. pneumoniae*, Stevens and associates[931] noted the following frequencies of symptoms and signs: cough, 97 percent; malaise, 82 percent; vomiting, 40 percent; abdominal pain, 35 percent; headache, 32 percent; rash, 20 percent; fever higher than 38° C (>100.4° F), 78 percent; rales, 78 percent; pharyngitis, 32 percent; rhonchi, 30 percent; bronchial breathing, 27 percent; and otitis media, 27 percent. Foy and coworkers[320] found that chills and productive cough were more common in adults than children and that temperatures tended to be higher in children.

In a large study involving 108 children with *M. pneumoniae* infection, wheezing occurred with the acute illness in 40 percent.[834] When the children in this study were evaluated 3 years after their acute illness, they were found to have three indicators of lung function that had mean values significantly lower than those in control children.

Few reports specifically describe pneumonia caused by *M. pneumoniae* in young children.* However, a review of the case descriptions available indicates that illness, when it occurs, can be severe and relatively prolonged in contrast to common viral and bacterial infections. Singer and DeVoe[896] reported a 3-year-old severely ill child who had a temperature of 39.4° C (102.9° F), a pulse of 150 beats/min, and a respiratory rate of 40 breaths/min. Diffuse pulmonary involvement of the right upper lobe and lingular segments of the left lower lobe was observed by radiography, although rales and altered breath sounds could not be heard. The patient's condition worsened over a 6-day period. At this time, specific therapy with erythromycin was instituted, and slow recovery followed. The child had a normal white blood cell count, transiently elevated serum aspartate aminotransferase and alanine aminotransferase values, and microscopic hematuria. Grix and Giammona[374] observed two 5-year-old children with extensive pneumonia, pleural effusions, and febrile periods of 10 and 16 days. Stevens and associates[931] reported a 5-year-old boy with pulmonary consolidation and aseptic meningitis, and Clyde and Denny[190] described an asymptomatic 3-year-old boy with a "feathery infiltrate" in the right upper lung field. In a family study, Foy and colleagues[307] investigated four children younger than 6 years. In a 4-year-old child, the pneumonia persisted for more than 1 month, and in this child's brother, the illness lasted approximately 2 weeks. I have seen a 4½-year-old girl with scattered infiltrates throughout both lung fields and febrile illness of 14 days' duration.[159]

*References 39, 158, 190, 229, 307, 374, 713, 896, 931, 1064.

Severe and extensive pulmonary disease occurs occasionally in *M. pneumoniae* infection.* Massive lobar pneumonia is noted on occasion, and pleural effusions are fairly common findings.† A number of cases of necrotizing pneumonitis with massive pleural effusions have been described.[50,172,1027] All of these children had protracted periods of fever and respiratory distress. Acute respiratory distress syndrome has been observed, and illness has suggested pulmonary embolism with infarction.‡ Chronic intestinal pulmonary fibrosis and fulminant fatal diffuse interstitial fibrosis has been noted in two adults with *M. pneumoniae* pneumonia, and localized bronchiectasis developed in a 20-year-old man at the site of previous acute lung infection.[171,359,478,942] Children who had a delay in onset or inadequate duration of macrolide treatment were found by Marc and associates[630a] to have reduced lung diffusion capacity after contracting *M. pneumoniae* pneumonia. Barreira and associates[50] describe a previously health 8-year-old boy who developed necrotizing pneumonitis, septic shock, and meningoencephalitis from *M. pneumoniae*. A 5-year-old girl had severe necrotizing pneumonitis, and an adult had bronchiolitis obliterans–organizing pneumonia.[592,750] *M. pneumoniae* pneumonia is generally more severe in patients with preexisting cardiorespiratory problems, immunodeficiencies, and sickle-cell disease.§

Five patients—two children, one adolescent, and two adults—were found to have lung abscesses in association with *M. pneumoniae* infection.[171,570,576,891] The illness in the adolescents and adults was characterized by productive cough and chest pain for 2 to 4 weeks. In one patient, clinical recovery and clearance of the pulmonary lesion were dramatic with tetracycline therapy; two other patients received suboptimal therapy but eventually recovered. One of the child cases was a 6-year-old girl who had a 7-day history of cough and a 4-day history of fever.[171] In addition to the abscess, she had pleural effusion, thrombocytopenia, and disseminated intravascular coagulation. The other child was a 10-year-old boy with fever and cough for 15 days refractory to treatment with amoxicillin and ceftriaxone, but with rapid improvement on clarithromycin.[570] One 18-year-old man with extensive consolidation of the right lower lung field had residual pleural scarring 8 months after the acute illness.[701]

Newborns who contracted congenital pneumonia, probably via vertical transmission of *M. pneumoniae*, have been described.[916,989]

Clyde[189] reported factors that correlated with *M. pneumoniae* pneumonia in a study of 1139 subjects with community-acquired pneumonia. Positive factors were sore throat, headache, fever of 38.9° C (102° F) or higher, exanthem, family size of four or more, and ear infection. In the same study, pneumonia did not correlate with coryza, leukocytosis (15×10^9/L or more and 10×10^9/L or more), preexisting disease, recurrent pneumonia, hospitalization for treatment, or cigarette smoking.

Although recovery from *M. pneumoniae* pneumonia is usually complete, two studies suggest that persistent abnormalities in lung function can occur after illness.[689,834]

Radiography. Because the classic clinical entity primary atypical pneumonia has numerous causes but often is used as a synonym for *M. pneumoniae* pneumonia, much confusion has ensued about the spectrum of the radiographic appearance of the specific mycoplasmal infection. The radiographic pattern of primary atypical pneumonia is varied, but bilateral, diffuse, reticular infiltrates are common components.[599,863,899] Subsequent study has indicated that the diffuse interstitial pattern is an uncommon finding in *M. pneumoniae* infection and more often is the result of infection with other agents such as viruses, fungi, and *Chlamydia*.[106,341,727,800,983]

Brolin and Wernstedt[106] carefully evaluated the radiographic findings in 56 patients with significant *M. pneumoniae* pneumonia; 21 of the patients were younger than 20 years. They noted the following distribution of different patterns: typical lobar pneumonia, 8 patients; predominantly alveolar but not total consolidation, 13; interstitial (either reticular or noduloreticular), 20; a combination of lobar pneumonia and other alveolar involvement without total consolidation, 2; a combination of lobar involvement and interstitial, 10; and a combination of alveolar involvement without total consolidation and interstitial, 3. Alveolar patterns were more common in females; interstitial involvement was found more frequently in males. Twenty-two percent of patients had enlargement of the hilar or paratracheal lymph nodes, and 14 percent had pleural effusion.

The persistence of radiographic changes is variable. Brolin and Wernstedt[106] noted that 13 percent of their patients who underwent follow-up studies had abnormal findings more than 4 weeks after the initial study. They observed that persistence tended to be longer in patients with alveolar disease than in those with interstitial patterns. The degree of clinical symptoms and pulmonary physical findings frequently correlates poorly with the apparent degree of involvement noted on radiographs. In many patients with significant symptoms, only minimal interstitial changes are observed. In other instances, patients with lobar pneumonia often have few clinical findings indicating pulmonary disease.

Lee and colleagues[558] reported the chest computed tomography (CT) features in 11 children and 5 adults with *M. pneumoniae* pneumonia. The children had the following findings: lobar or segmental consolidation, 100 percent; pleural effusion, 82 percent; lymphadenopathy, 82 percent; and volume decrease of the involved lobe, 73 percent. None of the children had diffuse nodules of ground-glass attenuation, septal thickening, or bronchial wall thickening. In contrast with the children, the adults had diffuse nodules of ground-glass attenuation, 80 percent; septal thickening, 40 percent; lymphadenopathy, 40 percent; bronchial wall thickening, 40 percent; and volume decrease of the involved lobe, 20 percent. None of the adults had lobar or segmental consolidation and pleural effusion. In a retrospective analysis of 64 adult

cases of *M. pneumoniae* pneumonia in Japan, the most common CT findings were bronchial wall thickening (81%), followed by centrilobular nodules (78%), ground-glass attenuation (78%), and consolidation (61%).[681]

Kim and associates[505] performed high-resolution CT on 38 children who had been hospitalized with *M. pneumoniae* pneumonia 1 to 2.2 years previously. Abnormalities in two or more lobes, which corresponded to the initial chest radiographic infiltrates, were found in 37 percent of the children. Young age (<8 years) at the time of hospitalization and high *M. pneumoniae* antibody titer were found to be risk factors for the subsequent abnormalities.

Nonspecific Laboratory Data. The total leukocyte count in patients with pneumonia caused by *M. pneumoniae* is most often normal, but variation is considerable.* In a group of more than 250 children younger than 15 years, Foy and associates[320] noted that 30 percent and 6 percent had total leukocyte counts greater than 10,000 and 15,000 cells/mm^3, respectively. In a group of 45 children, Stevens and colleagues[931] observed leukocytosis in 33 percent of patients and leukopenia in one patient. Sixty-seven percent of the children had neutrophilia, and one patient had neutropenia. An increased percentage of band form neutrophils in *M. pneumoniae* pneumonia is an unusual finding.

The erythrocyte sedimentation rate is elevated in all cases,[76,200,457] and this elevation is usually marked. Biberfeld and colleagues[76] noted that 16/37 patients had erythrocyte sedimentation rates of 50 mm/hr. Serologic tests for syphilis are found to be falsely positive on occasion, and serum cold agglutinins and antibodies to *Streptococcus* MG antigen are common findings.[70,144,149,231] Results of the direct Coombs test are frequently positive, and elevated levels of serum IgM are noted.[70,284] Urinalysis results are generally normal.

Respiratory Disease Other Than Pneumonia

Common Cold and Unspecified Upper Respiratory Illness. By strict definition (i.e., significant nasal symptoms, no pharyngitis, and minimal fever), *M. pneumoniae* rarely causes the common cold. However, mild upper respiratory tract illness is noted frequently as the only manifestation of *M. pneumoniae* infection in children, adolescents, and young adults.† The frequency of unspecified upper respiratory tract illness as a manifestation of *M. pneumoniae* infection, in contrast to other manifestations resulting from infection with this agent, varies considerably among studies. Feizi[285] studied patients from a country practice in England and noted that 50 percent of the patients had upper respiratory tract symptoms. Illness in these persons often was prolonged, however, and lasted as long as 7 to 10 weeks. In a review in Scotland, only 3 percent of 596 *M. pneumoniae* infections were classified as upper respiratory tract illness. In studies of common respiratory tract illnesses in children in which viruses and other agents were sought, *M. pneumoniae* was noted in 2 to 5 percent of patients with upper respiratory tract illness.[147,231,597]

Pharyngitis and Nasopharyngitis. As noted in Table 195-2, pharyngitis is observed in approximately half of all patients with *M. pneumoniae* pneumonia. However, pharyngitis as the major manifestation of *M. pneumoniae* infection occurs less commonly. Parrott[776] found that 12 percent of children admitted to the hospital with severe "bronchitis-pharyngitis" had *M. pneumoniae* infection. Jensen and associates[466] noted the frequent occurrence of pharyngitis and otitis media in children infected with *M. pneumoniae*. In a study of 715 children and adolescents with pharyngitis, Glezen and colleagues[352] reported that 36.8 percent had group A streptococcal infection and 3.1 percent were infected with *M. pneumoniae*. When the *M. pneumoniae* infections were grouped by age, the peak (11.4%) occurred in the 12- to 14-year-old group and none were observed in children younger than 6 years. Five patients with *M. pneumoniae* infection had concomitant group A streptococcal infection, but the illnesses in these cases could not be distinguished clinically from those caused by either agent alone. Cervical lymphadenopathy occurred in approximately 50 percent of those infected, and the pharyngeal lesion was exudative in 43 percent. In a study of 127 children with acute pharyngitis, 25 (20%) were found to have serologic evidence of *M. pneumoniae* infection.[272] Seven (28%) of these children had pharyngeal exudates and 10 (40%) had cervical lymphadenopathy.

In a study involving 131 adult patients with pharyngitis, 10.6 percent were found to have serologic evidence of *M. pneumoniae* infection.[521]

Otitis Media and Bullous Hemorrhagic Myringitis. Although the incidence has varied across studies, otitis media is noted in approximately 5 percent of children and adolescents with *M. pneumoniae* pneumonia. The role of *M. pneumoniae* as an etiologic agent in common acute otitis media in children is unclear. Halsted and associates[386] noted that 12 percent of children with otitis media had serologic evidence of *M. pneumoniae* infection, but they were unable to recover the agent from middle ear fluid. In a study in which children were selected because of *M. pneumoniae* infection in a family member, 47 of 49 children with otitis media had *M. pneumoniae* infection.[466] Räty and Kleemola[808] used PCR to detect *M. pneumoniae* in 16/380 (4%) middle ear fluid samples from 138 children with acute otitis media.

In a volunteer study, myringitis developed in 13/52 subjects.[816] Findings were usually bilateral and associated with throbbing pain. The appearance of the tympanic membrane varied from mild injection to severe inflammation with edema. Hemorrhagic areas on the drum were noted in five subjects, and serous-appearing blebs containing blood were observed in two. Bullous myringitis also has been noted only occasionally with natural *M. pneumoniae* infection.* In one study of 148 children and adults with *M. pneumoniae* pneumonia, 27 (18%) were found to have bullous myringitis.[625] Using PCR, Kotikoski and associates[528] studied middle ear fluid from

†References 147, 202, 231, 248, 282, 285, 286, 294, 307, 317, 417, 555, 597, 686, 716, 735, 838.

*References 107, 190, 307, 317, 625, 907.

30 children and blister fluid from 12 children with acute meningitis and found no evidence of *M. pneumoniae* DNA.

Sinusitis. Although clinically recognized sinusitis has been reported rarely in patients with *M. pneumoniae* infection, Griffin and Klein[372] found radiographic evidence of sinusitis in approximately two thirds of a group of Navy recruits with *M. pneumoniae* pneumonia. In general, the patients with sinusitis had more prolonged illness than did recruits without sinusitis. Savolainen and colleagues[853] noted that 11/310 patients with acute maxillary sinusitis had fourfold or greater rises in complement-fixing antibody to *M. pneumoniae*. In chronic suppurative maxillary sinusitis, cultures for *M. pneumoniae* have been performed but no organisms were isolated.[68,915]

Acute Bronchitis. Acute bronchitis characterized by fever, cough, and rhonchi, with or without associated pharyngitis, is a frequent manifestation of *M. pneumoniae* infection.* Of 40 patients with *M. pneumoniae* infection, Feizi[285] reported that 6 had bronchitis, 3 had upper respiratory tract illness plus bronchitis, and 1 had sinusitis plus bronchitis. In contrast to these findings, Hornsleth[418] noted that only 1/25 patients with *M. pneumoniae* infection had acute bronchitis. In the differential diagnosis of acute bronchitis, *M. pneumoniae* infection accounts for 10 to 20 percent of cases.[145,148,231,276,789]

Croup. *M. pneumoniae* infection has been associated only occasionally with croup. Parrott[776] found no instances of *M. pneumoniae* infection in a large number of children with croup, and Chanock and Parrott[145] did not list this agent as an etiologic consideration in croup. In contrast, extensive studies in both Seattle and Chapel Hill, North Carolina, have revealed that approximately 2 percent of croup cases are associated with *M. pneumoniae* infection.[231,312,353,596] Because no descriptions of clinical illness are available, a reasonable assumption is that croup caused by *M. pneumoniae* infection is generally mild and without distinguishing characteristics.

Bronchiolitis and Infectious Asthma. The presence of *M. pneumoniae* in the lower airways can trigger a proinflammatory cytokine response similar to that seen in asthmatic and allergic patients.[392,662,666] *M. pneumoniae* pneumonia itself can cause bronchiolitis and wheezing[40,834]; however, it is also commonly found in asthmatics and is a cause of their symptomatic exacerbations.[67,430,703,766,878] Approximately 5 percent of cases of bronchiolitis are caused by infection with *M. pneumoniae*, but the percentage varies across studies.† In two large studies, no instances of *M. pneumoniae*–associated bronchiolitis were reported.[417,418] Horn and associates[703] noted that *M. pneumoniae* was isolated from 6.6 percent of children with wheezy bronchitis, and Berkovich and associates[67] found *M. pneumoniae* infection in 7/33 episodes of wheezing in asthmatic children. Biscardi and coworkers[79] studied children 2 to 15 years of age hospitalized for severe asthma. Of 119 children with previously diagnosed asthma, 24 (20%) had *M. pneumoniae* infections during the exacerbation that caused their hospital admission. In 51 children with first asthma episodes, *M. pneumoniae* infection was demonstrated in 26 (50%). Children with a first attack of asthma associated with *M. pneumonia* infection were significantly more likely to have asthma recurrences than children whose primary episodes were not related to *M. pneumoniae* infection. Lehtinen and colleagues[564] studied 220 children with wheezing associated with viral infection and found that 5 percent were coinfected with *M. pneumoniae*. Freymuth and colleagues[327] identified *M. pneumoniae* in nasal aspirate samples by PCR in 3/132 children (2%) with acute exacerbations of asthma.

Although a significant number of asthma exacerbations can be linked to *M. pneumoniae* infection, there is still conflicting evidence on the benefit of prophylactic or empirical antibiotic therapy in asthmatics.[525] Macrolides are sometimes advocated not only as an antibiotic but also for their anti-inflammatory properties.[357]

Other. Exacerbations of chronic obstructive pulmonary disease have been associated with *M. pneumoniae* infection.[168,545,661,903,1041] By culture, Cherry and associates[168] did not obtain any *M. pneumoniae* isolates from the bronchial specimens of adults with chronic bronchitis. However, more recently, Kraft and colleagues,[531] using PCR, detected *M. pneumoniae* in the bronchoalveolar lavage or bronchial biopsy specimens of 9/18 adults with chronic asthma. Smith and associates[902] were unable to show that patients with chronic obstructive pulmonary disease had increased susceptibility to infection in contrast to normal subjects. Illness suggestive of pertussis has been described in three children.[547,931] Teig and associates[961] studied nasal brush specimens and induced sputum from 38 children with stable chronic lung disease and 42 healthy controls for the presence of *M. pneumoniae* DNA by PCR. Specimens from 4 (10.5%) of the children with chronic lung disease had *M. pneumoniae* DNA, whereas none of the specimens from control patients were positive. In two provocative studies, Esposito and coworkers[273,274] found that *M. pneumoniae* infections may play a role in recurrent respiratory infections in children. In their studies, they found that children with tonsillopharyngitis or other respiratory infections caused by *M. pneumonia* who were treated with azithromycin 10 mg/kg/day for 3 days weekly for 3 weeks were significantly less likely to have recurrent respiratory tract infections than children with similar *M. pneumoniae* infections who did not receive azithromycin treatment.

Exanthem and Enanthem

Exanthem as a manifestation of *M. pneumoniae* infection is a common occurrence, but its incidence has varied considerably among different studies.* In large studies involving children in which *M. pneumoniae* infection was evaluated in a specific geographic area, the incidence of exanthem has varied from 3 to 33 percent.† Foy and

†References 200, 286, 307, 317, 417, 457, 547, 612, 625, 716, 735, 922, 931.

associates[317] noted rash in 17 percent of 319 patients with *M. pneumoniae* pneumonia during a 5-year surveillance period. In a study involving only children, Stevens and colleagues[931] noted exanthem in 9 percent of their patients. Copps and coworkers,[200] in a community outbreak in La Crosse, Wisconsin, found that 11 percent of their patients with pneumonia also had rash.

The cutaneous manifestations in *M. pneumoniae* infection are protean. Most common is an erythematous maculopapular rash that is most prominent on the trunk and back; the lesions may be discrete (rubelliform) or confluent (morbilliform). Although not the most common cutaneous manifestations of *M. pneumoniae* infection, erythema multiforme and Stevens-Johnson syndrome are the most often reported and the most serious.* In Table 195-3, the clinical findings in 29 well-documented cases of *M. pneumoniae* infection with exanthem are presented. Of the total group, all but 8 were males, 24/29 were younger than 20 years, and 12/20 were younger than 11 years. The duration of exanthem was longer than 7 days in all but 2 patients; all patients were febrile, and in 17 cases, the rash occurred during fever.

Enanthems are also common with *M. pneumoniae* and have been given their own name—*Mycoplasma pneumoniae*–associated mucositis (MPAM).[852] Oral lesions appear most frequently, followed by ocular and urogenital findings. Because cutaneous involvement is not always concurrently seen, some also to refer to this syndrome as an "atypical Stevens-Johnson" or "Fuchs syndrome."[654,857,668,806] In Table 195-4 the specific mucocutaneous findings in 20/29 patients are itemized. Of these, 14 patients had generalized ulcerative stomatitis and 7 had tonsillitis or pharyngitis. Severe conjunctivitis was observed in 8 patients, and this manifestation was seen only in those with vesicular or bullous cutaneous lesions. All 8 patients with severe conjunctivitis also had generalized ulcerative stomatitis. Surprisingly, vesicular or bullous exanthems with oral and eye lesions (i.e., Stevens-Johnson syndrome) rarely occur in females.[40,641,931] Mucocutaneous findings also are present in vasculitic disorders such as Kawasaki disease and Behçet syndrome, and both of these have also been associated with *Mycoplasma* infection.[258,560,1002,1074] As noted in Table 195-3, 25/29 patients had pneumonia. The occurrence of rash as the major manifestation of *M. pneumoniae* infection is probably rare. In a study of 112 patients who had suspected infectious exanthems without pneumonia, Cherry and associates[166] could find none with *M. pneumoniae* infection. Foy and colleagues[307] noted a 2-year-old child with only rash, Stutman[935] reported a 15-year-old boy with Stevens-Johnson syndrome but not pneumonia, from whom the organism was recovered from a vesicular lesion. Ruhrmann and Holthusen[830] observed frequent cases of mild erythema multiforme without pneumonia.

In an analysis of 42 cases of erythema multiforme seen during a 20-year period, Villiger and associates[998] noted a presumptive or definite diagnosis of *M. pneumoniae* infection in 14 children. Nine of the children were boys (64%), and eight of the illnesses had mucous membrane involvement.

Many patients with *M. pneumoniae* infection and exanthem have a history of antibiotic administration before development of the rash; this observation suggests the possibility that the rash is drug induced rather than a

result of the infectious process. As noted in Table 195-3, 17 patients had received antibiotics before the rash appeared, and the exanthem was present before the administration of antibiotic therapy in 10. Although these data incriminate the infection as a cause of exanthem, the large number of cases in association with the administration of antibiotic raises the possibility that the antibiotic intensifies the dermosensitive potential of the infectious agent in a manner similar to that noted between Epstein-Barr virus and ampicillin in infectious mononucleosis. *M. pneumoniae* has been recovered from the blister fluid of two patients with erythema multiforme.[607]

Other unusual cutaneous manifestations include erythema nodosum, pityriasis rosea, varicella-like urticaria, papular purpuric gloves and socks syndrome, and Cockade purpura.*

Cardiac Manifestations

Cardiac involvement during *M. pneumoniae* infection generally is considered to be unusual.† However, studies of Pönkä[791] and Sands and associates[848] and survey data of Noah[742] and Assaad and Borecka[33] indicate that *M. pneumoniae* myocarditis and pericarditis are important causes of both morbidity and mortality. In a study of fatal viral and mycoplasmal infections, Assaad and Borecka[33] noted six cardiovascular deaths related to *M. pneumoniae* infection during a 9-year period. Noah[742] found that 1 percent of 700 patients with *M. pneumoniae* infection had cardiac manifestations as the main clinical feature. Pönkä[791] published findings of a 7-year study involving 560 patients with serologic evidence of *M. pneumoniae* infection. In this group, 69 patients with cardiac manifestations were detected; of these 69 patients, 25 had carditis for which no causal agent other than *M. pneumoniae* could be incriminated. Pönkä[791] also reviewed the world literature and found a total of 33 other cases of carditis.

Of 25 carefully studied patients, 17 had respiratory symptoms before the diagnosis of carditis and 10 had radiologically confirmed pneumonia. All but four patients had fever. Of the 25 patients, 2 were younger than 10 years and 2 were in the 10- to 19-year-old age group. Of the 33 cases in the literature, 7 were 20 years or younger. Of this survey group, 25/33 had respiratory illness and in 19 it was recorded as pneumonia.

Of the 25 patients in Finland reviewed by Pönkä, 6 had pericarditis and the remainder had perimyocarditis. Antibiotic therapy in 11 patients did not appear to shorten the duration of illness or diminish the number of cardiac sequelae. At a 16-month follow-up, 11 patients had persistent cardiac damage. Another interesting aspect of this study was the finding of rises in *M. pneumoniae* complement-fixing antibody titer in 5 adults with myocardial infarcts.

Chergui and associates[157] described a 45-year-old man with bilateral interstitial infiltrates and second-degree heart block. He was treated with erythromycin, and the heart block, fever, and respiratory distress cleared on hospital day 5.

Mycoplasma may also affect the heart through vasculitis, valvular disease, atherosclerosis, and coronary artery

disease, although there are conflicting data on the subject.[58,223,377,615]

Hematologic Manifestations

Severe hemolytic anemia has been reported on several occasions in patients with *M. pneumoniae* infection.* Most cases of *M. pneumoniae* hemolytic anemia have been associated with marked pulmonary involvement. Stevens-Johnson syndrome is a common associated finding, and myocarditis has been noted on two occasions.[199,283,285,502,931] In general, severity of illness correlates with high titers of cold agglutinins. One unusual case of a 2-year-old boy with severe *M. pneumoniae* IgM-mediated hemolytic anemia without pulmonary symptoms was described.[529]

The hemolysis may be severe and acute, often with a 50 percent reduction in hemoglobin concentration. In contrast to uncomplicated pulmonary disease, the leukocyte count in patients with hemolytic anemia frequently is elevated markedly with a predominance of neutrophils. Results of the direct Coombs test are usually positive. Clinical experience suggests that administration of steroids in conjunction with proper antibiotic therapy may be beneficial in this illness. Boccardi and associates[91] observed a 7-year-old boy with hemolytic anemia and transitory paroxysmal cold hemoglobinuria.

Feizi[284] has demonstrated that clinically inapparent compensated hemolysis frequently is associated with *M. pneumoniae* pulmonary infection. Fiala and associates[297] noted that bone marrow suppression also contributed to the anemia in a patient whom they studied, and pancytopenia has also rarely been described.[381] Ruhrmann and Holthusen[830] reported a hemorrhagic variant of erythema multiforme (Cockade purpura) similar to Henoch-Schönlein disease in *M. pneumoniae* infection; they also noted severe thrombocytopenia not associated with hemolytic anemia. Gill and Marrie[347] reported a 27-year-old man who had hemophagocytosis with an *M. pneumoniae* infection. Two children with hemophagocytic lymphohistiocytosis in association with *M. pneumoniae* infections have been reported.[442] Also noted has been a 4-year-old girl with neutropenia, thrombocytopenia, and acute hepatitis.[154] Severe *M. pneumoniae* infection with pneumonia, thrombocytopenia, and disseminated intravascular coagulation (DIC) has been described.[171,177] Hypercoagulability resulting from *M. pneumoniae* infection with evidence of autoimmune antibodies has manifested as venous thrombosis and pulmonary embolisms in several cases.[31,36,44,108,365] Aviner and colleagues[36] also describe eight cases of *M. pneumoniae* infection with associated thrombocytopenia not related to DIC.

Gastrointestinal Findings

Nonspecific Findings. Approximately 25 percent of patients with *M. pneumoniae* pneumonia have nausea, vomiting, diarrhea, or some combination thereof (see Table 195-2). Aside from these complaints, gastrointestinal problems in association with *M. pneumoniae* infection are rare events. Stevens and associates[931] found that 15 percent of a group of 44 children with infection had notable abdominal pain. Referred abdominal pain with pneumonia also has been observed.[285]

Liver Involvement. Liver involvement in *M. pneumoniae* infection is a surprisingly rare event. Levine and Lerner[574] reported that mild increases in transaminases occur and that acute and chronic active hepatitis has been noted with respiratory symptoms and proved *M. pneumoniae* infection, but they provided no further information. MacLean[612] reported a 13-year-old girl who initially had a sore throat and 9 days later had clinical and laboratory evidence of hepatitis. Murray and associates[706] presented a case report of an adult with typical *M. pneumoniae* pneumonia in whom liver function and enzyme studies indicated hepatitis. Helms and colleagues[403] noted that 6/17 patients with *M. pneumoniae* pneumonia had elevated aspartate aminotransferase values. Enzyme changes have been observed in other case evaluations,[576,625,896] some with coagulopathy,[142] and hepatic necrosis has occurred.[616,704]

Simonian and Janner[894] reported a 12-year-old boy who had pleural effusion, hepatitis, and hemolytic anemia. Narita and associates[726] noted two children with lymphadenopathy and liver dysfunction. These two patients are of interest because both had mycoplasmemia and neither had pneumonia. Elevated liver enzymes without respiratory symptoms also have been found in young adults with elevated *M. pneumoniae* serologies.[560,803,825]

Splenic Infarct. Two children (a 13-year-old girl and a 10-year-old boy) with pneumonia resulting from *M. pneumoniae* infection had splenic infarcts and transient antiphospholipid antibodies.[1049] A 24-year-old man with an elevated *M. pneumoniae* IgM titer developed hepatosplenomegally and splenic infact.[773]

Pancreatitis. In 1974, Märdh and Ursing[630] reported six patients with respiratory tract illnesses, serologic evidence of *M. pneumoniae* infection, and pancreatitis. In four patients, pancreatic symptoms began 1 to 2 weeks after the onset of respiratory tract illness; in the other two patients, the pancreatitis was subclinical. Diabetes developed in two patients, one of whom died. At postmortem examination, pneumonitis and pancreatitis were confirmed. Nakagawa[714] and colleagues report on an 8-year-old girl who developed necrotizing pancreatitis 10 days into her treatment for *M. pneumoniae* pneumonia. In a study of pancreatitis, Leinikki and Pantzar[566] noted that sera from 18/56 patients had rises in complement-fixing antibody titer to *M. pneumoniae*. Because none of the patients in this study had respiratory tract illness suggestive of *M. pneumoniae* infection, the investigators suggested that perhaps the antibody responses were not specific for *M. pneumoniae* infection but were caused by a cross-reacting infection or were the result of autoantigens from pancreatic damage. Leinikki and associates[567] have conducted further studies; their thought is that the antibody response is nonspecific, but their data neither confirm nor refute this assumption. In another study, Freeman and McMahon[325] also noted serologic evidence

*References 155, 157, 165, 279, 283, 331, 367, 496, 501, 502, 529, 546, 575, 598, 711, 741, 770, 941, 1051.

of *M. pneumoniae* infection in 33 percent of patients with pancreatitis. Oderda and Kraut[749] reported a 22-month-old girl with pancreatitis and a rise in complement-fixing antibody titer to *M. pneumoniae*. This child had no respiratory symptoms.

Arthritis

Mycoplasmas are a common cause of arthritis in animals other than human beings.[194,456] Likewise, *M. pneumoniae* infection is associated occasionally with joint manifestations.* In a review of 1259 patients with *M. pneumoniae* infection, Pönkä[790] noted transient arthritis in 0.9 percent. Two patients were found to have Reiter syndrome. Hernandez and colleagues[407] reported seven instances of arthritis in 38 persons with *M. pneumoniae* respiratory disease. In one patient, the illness lasted 18 months and was associated with the development of rheumatoid factor.

Twenty-one instances of illness suggestive of rheumatic fever have been described.† In all 21 patients, large joints were involved; 18 patients had joint swelling or effusion, whereas 3 had only pain. Most patients had a history of preceding respiratory illness with sore throat, and 10/21 had radiographic evidence of pneumonia. The sedimentation rate was elevated in all patients in whom the test was performed. One child had an erythema marginatum–like rash, as well as polyarthritis and fever.[693] Poggio and colleagues[788] reported a child with reactive arthritis 3 weeks after the onset of diarrhea and a respiratory tract infection. Leukocytoclastic vasculitis plus polyarthritis associated with *M. pneumoniae* infection has been described in a young adult.[784]

Muscular Disease

Berger and Wadowksy[66] reported a 15-year-old girl with right lower lobe pneumonia, hepatitis, and rhabdomyolysis associated with *M. pneumoniae* infection. Minami and associates[675] reported a 4-year-old boy with pneumonia and a rhabdomyolysis associated with a marked titer rise to *M. pneumoniae* using a passive agglutination assay. Oishi and associates[754] described a case of multidrug resistant *M. pneumoniae* causing rhabdomyolysis in a 7-year-old girl. Polymyositis has been noted in association with *M. pneumoniae* infection on six occasions.[783]

Neurologic Disease

Several large community and military studies of *M. pneumoniae* pneumonia and other respiratory tract illnesses are notable in that neurologic disease is not described.‡ However, other studies, particularly those performed more recently, indicate a surprising spectrum of neurologic illness associated with *M. pneumoniae* infection.§ The failure to find neurologic disease in the initial large studies mentioned was probably due not to its absence but to the orientation of the investigators; neurologic disease was not studied under the respiratory investigation protocols. In three large studies of *M. pneumoniae* illness involving 1856 cases, 2.6 to 4.8 percent had neurologic illness.[735,742,793] Assaad and Borecka[33] noted five fatal *M. pneumoniae* infections in which central nervous system (CNS) findings were the major clinical manifestations.

In 1973, Lerer and Kalavsky[573] reported 5 cases of neurologic disease associated with *M. pneumoniae* infection and analyzed 45 cases from the literature. They noted the following frequencies of specific clinical involvement: generalized encephalitis, 30 percent; spinal nerve roots, 30 percent; meningitis, 20 percent; cranial nerves, 20 percent; focal encephalitis, 16 percent; cerebellum, 14 percent; psychosis, 8 percent; and spinal cord, 2 percent. Combined involvement was noted in 36 percent of cases; in 79 percent, a history of antecedent respiratory illness was elicited. Of the patients, 53 percent were 20 years or younger, and 15 percent were younger than 10 years. Eighty percent of the children and adolescents were males. The onset of neurologic disease occurred 3 to 23 days after the onset of respiratory illness, with a mean value of 10 days. Five deaths were noted, and 22 percent of the survivors had residual neurologic deficits.

In a review of 61 patients with *M. pneumoniae*–associated neurologic disease during a 24-year period in Helsinki, Finland, Koskiniemi[527] noted that 45 of the patients were children and that all these children had encephalitis. Of the total group, 5 patients (8%) died and 14 (23%) had severe sequelae.

In a study of acute childhood encephalitis in Toronto, Canada, 9/50 children (18%) with adequate microbiologic study had evidence of *M. pneumoniae* infection.[520] Interestingly, 4 of the 9 children also had evidence of concomitant viral infection. In a further study of encephalitis at the same center during a 5-year period, researchers noted that 50/159 children (31%) with encephalitis had evidence of *M. pneumoniae* infection[81]; in this analysis, 30 of the 50 cases (60%) had microbiologic evidence of other concomitant infections. Respiratory prodromal symptoms preceded the encephalitis in approximately 67 percent of the patients in whom the diagnosis was based on culture, PCR, or both. Two children had acute demyelinating encephalomyelitis. Long-term neurologic sequelae occurred in 48 to 64 percent of cases. From 1998 to 2006, 1988 patients with encephalitis of unclear etiology were referred to the California Encephalitis Project (CEP).[176] *M. pneumoniae* was the most common agent implicated; 111 patients had evidence of *M. pneumoniae* infection, and 84 (76%) of these patients were children. In recent years, the CEP began to detect an increasing number of cases of anti–*N*-methyl-D-aspartate receptor (anti-NMDAR) encephalitis among children,[329] an autoimmune process that in some cases has been linked to *M. pneumoniae* infection.[328]

In other studies, aseptic meningitis is reported more frequently; other less common findings include poliomyelitis-like syndrome, bilateral sensorineural

deafness, Reye syndrome, cerebral infarction, optic disk swelling, opsoclonus-myoclonus syndrome, brain stem syndrome, transverse myelitis, psychosis, cerebellar syndrome, radiculopathy, brachial plexus neuropathy, demyelinating polyneuropathy with syndrome of inappropriate secretion of antidiuretic hormone (SIADH), acute disseminated encephalomyelitis (ADEM), bilateral striatal necrosis, Kluver-Bucy syndrome, Tourette syndrome, obsessive-compulsive disorder, hydrocephalus and intracranial hypertension, Bell palsy, and Guillain-Barré syndrome.

Arthur and Margolis[30] noted the appearance of *Mycoplasma*-like structures in granulomatous angiitis of the CNS at postmortem examination of a 35-year-old man.

Mixed Infections

In many studies of *M. pneumoniae* infection, cultural or serologic evidence of concomitant or sequential infection with other infectious agents has been noted.* In a large study of patients hospitalized with acute respiratory illness, Fransen and associates[323] found that 64 percent of patients with rises in complement-fixing antibody titer to *M. pneumoniae* also had antibody titer rises to viral, chlamydial, or bacterial agents. In this group, the most common concomitant infections were with parainfluenza viruses. The occurrence of mixed infection did not appear to have a pronounced effect on clinical manifestations; the only significant difference between patients with mixed infection and those with single *M. pneumoniae* infection was the more common finding of a high erythrocyte sedimentation rate in the former group. In several other large studies of disease caused by *M. pneumoniae*, concomitant infections were common, but no evidence of synergistic or antagonistic roles of one agent for another was noted.[286,352,686,921,922] By contrast, Johansson and associates[467] did observe more severe disease in patients with mixed viral and bacterial infections, including *M. pneumoniae*, than those with bacteria alone.

Renner and associates[814] found a lower than expected frequency of seropositivity to *M. pneumoniae* in 91 serum pairs with seroconversion to influenza A virus.

The high rate of possible mixed infections in the large encephalitis study in Toronto is of particular interest.[81] In addition to common respiratory viruses and enteroviruses, they noted herpes group viruses, *Bartonella henselae*, and *Mycobacterium tuberculosis*. Similar to *M. pneumoniae*, *M. tuberculosis* is also able to induce cold-agglutinins and hemolytic anemia, and other cases of dual infection with both organisms have been described.[1050] In studies of *Bordetella pertussis* infection, evidence of mixed infection with *M. pneumoniae* or perhaps serologic cross reactivity has been found repeatedly.[446,999,1073] Vervloet and colleagues[996] found that of 44 cases of *M. pneumoniae* pneumonia, 9 had concomitant *S. pneumoniae* infection.

The observation by Grady and Gilfillan[361] that 81 percent of patients with legionnaires' disease also had serologic evidence of *M. pneumoniae* infection is interesting. In the same study, 29 percent of all patients seropositive for *M. pneumoniae* also were seropositive for the legionnaires' disease antigen. Comparable studies performed by the Centers for Disease Control and Prevention failed to find a similar rate of high co-positivity in sera obtained in other legionnaires' disease epidemics. Another study found no serologic relationship between *M. pneumoniae* and *Legionella pneumophila*.[813] Severe bacterial disease after *M. pneumoniae* infection has been reported occasionally. Stadel and colleagues[917] noted *Hemophilus influenzae* pneumonia and bacteremia after a mild *M. pneumoniae* illness; Biberfeld and colleagues[77] reported staphylococcal septicemia in two cases of *M. pneumoniae* pneumonia, and Rykner and associates[832] recovered pneumococci from the pleural exudate of a patient with *M. pneumoniae* pneumonia.

Kleemola and Kayhty[511] found fourfold or greater increases in *M. pneumoniae* complement-fixing antibody titer in 40.7 percent of 54 patients with bacterial meningitis. However, they thought that this antibody response was not caused by specific *M. pneumoniae* infection but by cross-reactive glycolipids resulting from the bacterial infection.[511,512]

Lind and associates[586] reported that 4/19 patients with neurologic disease and *M. pneumoniae* infection had serologic evidence of concomitant viral infection. Wang and colleagues[1026] discovered that 3/22 children with *M. pneumoniae*–positive PCR assay also had a positive PCR for respiratory viruses.

Other Disease Associations

Foy and colleagues[307] noted that both ear involvement and pneumonia as manifestations of *M. pneumoniae* infection occurred more commonly in children with previous tonsillectomy. Putman and associates[799] found that in all but 3/31 patients with sarcoidosis, the serum complement-fixing antibody titer to *M. pneumoniae* was 1:32 or higher, whereas in a similar-sized control group without sarcoidosis, only 2 persons had titers of 1:32 and none had higher titers. Other interesting observations include multiple birth defects in a newborn exposed to *M. pneumoniae* in utero,[100] a tubo-ovarian abscess in a young woman from whom *M. pneumoniae* was isolated in pure culture,[969] fever of unknown origin in a 32-year-old man,[538] glomerulonephritis in a few patients with pneumonia,[9,793] SIADH in a 6-year-old boy,[589] acute IgA nephropathy,[938] and optic disk swelling and iritis.[840]

Recurrent Disease

The results of several investigations suggest that recurrent *M. pneumoniae* infection is a frequent finding.[113,295,928] Repeat infections can be associated with severe disease such as pneumonia. In the Seattle studies, second attacks of pneumonia have been documented, and similar findings have been observed in England.[309,319,321,417] Recurrent *M. pneumoniae* infections also occurred throughout the lifetime of a child who was immunocompromised from both poorly controlled human immunodeficiency virus (HIV) and B cell lymphoma therapy, and died at 8 years of age.[1035]

*References 12, 40, 39, 263, 286, 287, 324, 352, 361, 370, 383, 446, 447, 514, 520, 572, 583, 626, 634, 686, 723, 814, 917, 921, 922, 996, 997, 999, 1026, 1037, 1073.

Disease in the Neonate

M. pneumoniae is a common cause of respiratory infection beyond the neonatal period; however, rare cases of intrauterine infection leading to pneumonia in infancy have been found.[916,990]

Diagnosis

Differential Diagnosis

Because the clinical manifestations of *M. pneumoniae* infection are protean and because infections occur commonly in children and adolescents, this agent should be considered in the differential diagnosis of most infectious illnesses. Most important is its consideration in patients with pulmonary disease, in whom illnesses caused by viruses (particularly adenoviruses, parainfluenza viruses, and influenza viruses), *Chlamydia psittaci*, *Chlamydia pneumoniae*, *Coxiella burnetii*, bacteria (particularly *Streptococcus pneumoniae*, *B. pertussis*, *H. influenzae*, and *M. tuberculosis*); and fungi (particularly *Histoplasma capsulatum* and *Coccidioides immitis*) are the main differential possibilities. Because the clinical manifestations, including the radiographic appearance of the lungs, are frequently similar in the various differential possibilities, the following other factors are important: status of the host (i.e., normal or immunologically compromised), the environment (i.e., human, animal, or inanimate source), the age of the patient, the incubation period, and the season.

In otherwise healthy children, *M. pneumoniae* is a common cause of pneumonia in those older than 3 years and is the leading cause of pneumonia in older children and adolescents. The lack of coryza is sometimes useful in differentiating *M. pneumoniae* pneumonia from that caused by common viral agents, and elevation of the white blood cell count along with an increase in band form neutrophils is evidence against a mycoplasmal etiologic agent, except in patients with concomitant hemolytic anemia. The occurrence of exanthem and, in particular, Stevens-Johnson syndrome should lead the physician to suspect *M. pneumoniae;* similarly, the occurrence of hemolytic anemia, joint manifestations, or neurologic signs and symptoms with pneumonia should lead the physician to strongly suspect *M. pneumoniae* as the etiologic agent. Because the pulmonary manifestations of *M. pneumoniae* infection are not always clinically apparent, a physician investigating an unusual acute or subacute case (i.e., aseptic meningitis or other neurologic illness; exanthem; enanthem; hepatitis; pancreatitis; pericarditis, myocarditis, or both; and arthritis) would be wise to consider the possibility of *M. pneumoniae* as the etiologic agent and to obtain appropriate chest radiographs, as well as definitive cultures and serologic studies.

Specific Diagnosis

Serum Cold Agglutinins. Despite the considerable confusion in the literature and by physicians in general regarding the diagnostic value of the serum cold agglutination test for *M. pneumoniae* infection, my opinion is that when it is used appropriately, the test is a simple and useful procedure. One cause for confusion was a report in 1966 in which only 1/28 children with positive cold agglutination titers actually had serologic evidence of *M. pneumoniae* infection by complement fixation.[937] However, this report can be criticized because the study population consisted of 444 children younger than 4 years of age and only 170 of this group had pneumonia. Because cold agglutinins are noted occasionally in the sera of patients of all ages with a variety of illnesses, for useful results, their study should have been restricted to patients likely to have *M. pneumoniae* lower respiratory tract disease.[167,299,342,582] In various studies of pneumonia, serum cold agglutinins at a titer of 1:32 or higher were found in 50 to 90 percent of patients with *M. pneumoniae* infection.* In general, the cold agglutinin response correlates directly with the severity of pulmonary involvement; patients with extensive lobar involvement nearly always have positive titers[8] (1:32), whereas those with only minimal findings on radiographic study frequently have equivocal or negative titers. Positive cold agglutination titers have been observed in 18 percent of adenoviral pneumonias in a study involving a military population.[342] In general, the higher the cold agglutinin titer, the more likely that a particular illness is caused by *M. pneumoniae*.

A rapid screening test for cold agglutinins is available and useful.[337,371] This test is performed by adding 4 drops of blood to a tube containing sodium citrate or another anticoagulant. The tube is placed in ice water (0° to 4° C [32° to 39.2° F]) in a freezer for approximately 30 seconds and then examined immediately for coarse agglutination by tilting the tube on its side. When the tube is warmed, the agglutination should resolve, and it can be reproduced again by repeating the ice water cooling procedure. A modified version of this rapid test was used in 126 children in an emergency department who had asthma exacerbations.[143] The test had a sensitivity of 78.3 percent and a specificity of 41.3 percent in contrast to an IgM ELISA.

Specific Antibody Determinations. Several specific antibody tests (i.e., growth inhibition, immunofluorescence, indirect hemagglutination, precipitation, mycoplasmacidal antibody, complement fixation, ELISA, adherence inhibition assay, radioimmunoassay, and radioimmunoprecipitation) can be used to measure serum antibodies to *M. pneumoniae*. In the past only the complement-fixation test was available routinely. A fourfold rise in complement-fixation antibody titer indicates acute *M. pneumoniae* infection. Because complement-fixation antibody in *M. pneumoniae* infection is of relatively short duration, the observation of a fourfold fall in titer also can be useful on occasion in assigning etiologic significance in a particular illness. High single titers (≥1:256) usually indicate recent infection but rarely can be used to relate the cause of an illness specifically to *M. pneumoniae*. Because *M. pneumoniae* infection is associated with a relatively long incubation period, the development of antibodies is occurring at the time of acute disease. As a consequence, fourfold changes in titer can occur in a short interval (5 days), and collection of paired sera 5 to 7 days apart usually reveals a significant rise in complement-fixation antibody titer.

*References 73, 144, 149, 324, 342, 457, 700, 931, 993.

Most diagnostic laboratories have replaced the complement-fixation test with commercial immunofluorescence or ELISA for demonstration of antibodies to *M. pneumoniae* antigens.* These tests, in addition to demonstrating rises in antibody values in paired sera, can identify specific IgM and IgA antibodies in single serum samples. In general, when used by experienced laboratory personnel, both immunofluorescence and ELISA have sensitivities and specificities similar to those of the complement-fixation test for determining significant increases in antibody values in paired serum specimens. In addition, demonstration of specific IgM or IgA antibody in a single serum sample suggests a recent infection. Today the most common method used for diagnosing *M. pneumoniae* infection in clinical practice in the United States is the single serum IgM assay (although PCR assay is becoming more frequent in the hospital setting). It should be pointed out that most available serologic tests have low specificity and that overdiagnosis is common[61,213,253,739,946]; therefore, new panels of antigens are being developed.[252] Furthermore, the specific IgM and IgA responses after infection may last for several months; therefore, demonstration of these antibodies in a single serum sample may be misleading with regard to the diagnosis of specific illness. Hence, in most instances, paired sera (i.e., 5 to 14 days apart) should be examined to confirm a clinical diagnosis. Also useful is the determination of cold agglutinin titers at the time of IgM ELISA. If an ELISA IgM test is positive and a cold agglutinin test is negative, the physician should be skeptical of the former value.

Culture. With proper media, experienced personnel have little difficulty isolating *M. pneumoniae* from throat swabs of infected patients.[18,980] However, because *M. pneumoniae* is relatively slow growing, in most instances requiring more than 1 week of incubation, culture is of less use for diagnosis of routine cases than is serologic study. Cultures should be performed in all unusual situations; specifically, joint fluid, CSF, pericardial fluid, and biopsy material should be cultured. The modified SP-4 medium, which is more sensitive than conventional *Mycoplasma* culture media, coupled with the agar plate immunofluorescence identification procedure, may assist the cultural diagnosis of *M. pneumoniae*.[980] However, low yield and sensitivity have caused some to recommend abandoning this diagnostic method.[876]

Detection by Polymerase Chain Reaction. A large number of studies have indicated the usefulness of PCR for demonstration of specific *M. pneumoniae* DNA in sputum, throat, nasopharyngeal, blood, CSF, urine, and tissue specimens.† Numerous different primers have been used to identify gene sequences of the P1 cytoadhesin protein, ATPase operon, 16S rRNA gene, and 16S-23 S rRNA spacer, p1 adhesin, tuf, parE, dnaK, pdhA, repMp1 noncoding element, and the CARDS toxin gene sequences.[1007]

Using culture plus serologic criteria as the comparative standard, several studies have shown excellent sensitivity and specificity. However, because both serology and PCR will occasionally give nonoverlapping false-negative results, a combination of these two diagnostic methods would be optimal.[485]

Treatment

Antimicrobial Therapy

M. pneumoniae is sensitive in vitro to erythromycin, tetracyclines, chloramphenicol, clarithromycin, azithromycin, several aminoglycosides, and quinolones.* It is resistant to all penicillins and for practical purposes to the cephalosporins. In spite of this demonstrated in vitro sensitivity of the organism, plus several studies that have shown clinical therapeutic effectiveness,† a common misconception of many physicians is that antibiotic therapy is of little value in the treatment of illness caused by *M. pneumoniae.* This idea had its origin before the present era, when many patients with viral pneumonia were given a diagnosis of primary atypical pneumonia and treated unsuccessfully with antibiotics.

In 1961, Kingston and associates[507] demonstrated the therapeutic effectiveness of demethylchlortetracycline for pneumonia caused by *M. pneumoniae*. Since then, several other antibiotics have been studied carefully and also have been found to be effective against *M. pneumoniae* pneumonia.‡ The drugs of choice for pneumonia caused by *M. pneumoniae* are either erythromycins or tetracyclines. Because of the adverse effects of tetracyclines on teeth, a macrolide is the drug of choice in children. In *M. pneumoniae* pneumonia, the dose of erythromycin for children is 40 to 50 mg/kg every 24 hours administered every 6 hours for a minimum of 10 days. For adolescents and adults, the dosage of erythromycin or tetracycline is 2 g every 24 hours administered every 6 hours. In general, the effectiveness of antibiotic therapy correlates directly with the severity of pneumonia and the elapsed time of illness before the initiation of therapy.

Azithromycin and clarithromycin both are approved for the treatment of community-acquired pneumonia in children.[89,390] Their advantage is less frequent dosing, shorter duration of therapy, and less gastrointestinal disturbance in older patients. The azithromycin dosing schedule is 10 mg/kg/day (maximal dose, 1 g/day) on day 1, followed by 5 mg/kg/day (maximal dose, 500 mg/day) for 4 days. The clarithromycin dose is 15 mg/kg/day administered every 12 hours for 10 days (maximal dose, 1 g/day). A growing number of macrolide-resistant strains of *M. pneumoniae* from clinical isolates

†References 89, 144, 231, 307, 317, 342, 457, 507, 830, 866, 871, 898, 901.
‡References 144, 231, 317, 342, 457, 830, 871, 898, 901.

have been noted in Japan since 2000, associated with mutations in the 23S rRNA gene.[638,696] These strains have since spread worldwide, with a rate of 8.2 percent resistance found in the United States between 2007 to 2010.[126,1053] In such cases, minocycline or levofloxacin have become preferred choices of therapy.[490] Ciprofloxacin also has been used successfully,[603] although it carries a small risk for tendonitis.

In all other clinical manifestations of *M. pneumoniae* infection except pneumonia (e.g., nonpulmonary respiratory infection, neurologic disease, and Stevens-Johnson syndrome), antibiotic therapy has not been evaluated adequately. In general, otitis media, pharyngitis, croup, and bronchiolitis appear to be mild, self-limited illnesses that require no therapy. In more serious illness, such as Stevens-Johnson syndrome and neurologic disease, individual case studies have indicated little evidence of therapeutic benefit with either erythromycin or tetracycline therapy. However, my opinion is that when diagnosed, most *M. pneumoniae* infections should be treated because there is little to lose and in vitro data suggest the possibility of efficacy. Jensen and colleagues[466] noted that prophylactic administration of oxytetracycline to family contacts prevented disease but not infection. Azithromycin prophylaxis has been used successfully in two hospital outbreaks of *M. pneumoniae* pneumonia.[433,510]

Corticosteroid Therapy

Steroids have been used in the management of severe pulmonary disease, Stevens-Johnson syndrome, encephalitis, and hemolytic anemia. Although definitive data are lacking, several case studies suggest associated clinical benefit; steroids seem to be particularly useful in treating severe hemolytic anemia.

Two groups[559,948] reported on the use of prednisolone or methylprednisolone in the treatment of children with *M. pneumoniae* pneumonia in whom the clinical course worsened while receiving appropriate macrolide therapy. Corticosteroid treatment in these children was related to clinical and radiologic improvement. Cimolai[181] noted dramatic improvement in a 7-year-old girl treated with methylprednisolone, and in 1964 Copps[199] noted dramatic improvement in an adolescent with persistent fever, severe pneumonia, and hemolytic anemia when treated with a corticosteroid and erythromycin. Lu and accociates[603] successfully treated six cases of macrolide-resistant *M. pneumoniae* infection with ciprofloxacin and corticosteroids.

Intravenous Immunoglobulin

Intravenous immunoglobulin (IVIG) therapy has been used successfully in certain cases of severe refractory *M. pneumoniae* infection, especially when there is suspicion of an autoimmune process.[34,105,877,1063] It is also used in cases of *Mycoplasma*-induced Kawasaki disease.

A 6-year-old girl with brain stem and striatal encephalitis complicating *M. pneumoniae* pneumonia experienced neurologic improvement within 48 hours of administration of intravenous immunoglobulin.[837]

Plasmapheresis

Plasmapheresis has been used rarely to treat severe manifestations of *M. pneumoniae* disease, including transverse myelitis with psychosis[204] and glomerulonephritis.[9]

General Management

Children and adolescents with *M. pneumoniae* pneumonia should be discouraged from engaging in excessive physical activity during the acute illness and for a 2-week period during convalescence because clearance, as observed by radiography, is slow and lags behind apparent clinical well-being. Older children and adolescents should be advised of their contagiousness to others; this risk period exists as long as cough persists, even with successful antibiotic therapy.

Prevention

Because of the marked and prolonged morbidity associated with *M. pneumoniae* infection, which has been particularly troublesome in the military, much effort was directed toward the development of vaccines. In 1965 Jensen and associates[465] reported encouraging initial trials with an inactivated vaccine. In this study, significant rises in *M. pneumoniae* growth-inhibiting antibody titer developed in 25 of 30 volunteers. Later challenge studies with the same vaccine indicated that 9/10 volunteers with serum antibody were protected, but illness more severe than that in the unvaccinated control group occurred in vaccinees who did not have an antibody response after initial immunization.[900] This altered reactivity on challenge suggested a sensitization process perhaps similar to that observed with other inactivated antigen vaccines and indicated the need for caution in further trials.[208,295] Additionally, because of the large incidence of autoantibody formation in *M. pneumoniae* infection, autoimmune sequelae could potentially be a significant adverse effect with these vaccines.[468] Other trials of inactivated vaccines in both adults and children have had varying degrees of success.[580,667,687,1039]

A trial with a live attenuated vaccine (i.e., a temperature-sensitive mutant) gave encouraging results.[368] However, because further study of natural *M. pneumoniae* disease indicated that reinfection occurs commonly and because sensitization may play a role in pathogenesis, proceeding slowly in conducting further vaccine trials in children seems prudent.[294]

DNA vaccines encoding a fusion of the *M. pneumoniae* P1 protein with an *Escherichia coli* toxin were recently found to confer protection in mice.[1070,1071]

The degree of contagion of *M. pneumoniae* is relatively low, so isolation methods should be effective in preventing spread of disease. The studies of Jensen and associates[466] and the hospital azithromycin trials[433,510] indicate that in certain circumstances (in particular, high-risk subjects such as patients with sickle-cell disease and high-risk populations), prophylactic administration of antibiotics may be justified.

UREAPLASMA

Properties

Ureaplasmas (formerly T-strain mycoplasmas) are distinguished from all other members of the order Mycoplasmatales by their production of urease and their ability to hydrolyze urea.[765,881,882,955] The morphologic characteristics of *Ureaplasma* spp. in young liquid medium culture are similar to those of other mycoplasmas. Round-ovoid elements approximately 330 nm in diameter with a range of 100 to 850 nm are found; rod-shaped and filamentous structures also occur, and the latter have a length of 2 µm and a width of 50 to 300 nm.[84,881,1044] In clinical material, short, bacillary forms with monopointed ends are common findings. Organisms are surrounded by a single trilaminar membrane approximately 10 nm thick with pilus-like structures radiating from the surface. Multiplication occurs by a simple budding process and perhaps by binary fission.

On unbuffered standard *Mycoplasma* agar with a pH of 6.0, *Ureaplasma* spp. colonies are small (20 to 30 µm) and circular, with irregular borders, and grow downward into the agar.[881] On buffered agar, *Ureaplasma* spp. colonies are bigger and often have the "fried egg" appearance of typical large colony-forming mycoplasmas.[618]

Isolation of *Ureaplasma* spp. from clinical material is assisted by the demonstration of urease activity.[296,880,957] In liquid medium containing urea and phenol red, growth of *Ureaplasma* spp. results in the production of ammonia, with a resultant increase in pH and a change in color. Subculture from broth to agar medium that contains urea and manganese sulfate yields dark brown ureaplasmal colonies.

Epidemiology

The main reservoirs of human strains of Ureaplasma spp. are the genital tracts of adult men and women.* *Ureaplasma* spp. are sexually transmitted organisms that colonize the urogenital tract of women at rates of 30 to 80 percent.[99,262,649,957] One study found that pregnancy was associated with a higher rate of *U. urealyticum* carriage in the cervix in contrast to rates in nonpregnant women (26% vs. 15.3%).[38] High rates of colonization have been associated with younger age, lower socioeconomic status, sexual activity with multiple partners, black ethnicity, and use of oral contraceptives, although not with HIV status.[360]

In general, cervicovaginal colonization with *Ureaplasma* spp. and *M. hominis* during pregnancy is not predictive of adverse outcomes such as premature delivery, low-birth-weight infants, and spontaneous abortion.[137,173,270,360,1012] However, preterm labor has been associated with the altered microbial environment found in bacterial vaginosis, although there have been conflicting reports on whether genital mycoplasmas may play a role as well.[240,561] High-density genital ureaplasmal colonization has been associated with chorioamnionitis and preterm delivery.[5,477,761] It is capable of invading the upper genital tract in a subpopulation of women, as evidenced by their isolation from the endometrium,[548] placenta,[266,399,538] and amniotic fluid.* These organisms also have immunogenic surface lipoproteins that may trigger inflammatory reactions that lead to preterm premature rupture of membranes and/or preterm labor.[389,477,550,747,780]

Ureaplasma spp. have been associated strongly with histologic chorioamnionitis, postpartum fever, and endometritis.†

Infants become colonized during passage through the birth canal of an infected woman.[320,513,563,940,1012] With ruptured membranes, the infant can be infected in utero.[513] *Ureaplasma* spp. have been recovered from the following sites in newborn infants: throat, nose, genitourinary tract of girls, urine of boys, external auditory canal, umbilicus, and perineum. Not all infants of infected women become colonized, and neonatal colonization tends to not persist. In one study in which *Ureaplasma* spp. were recovered from 38 percent of girls and 6 percent of boys at birth, follow-up during a 2-year period revealed a decreasing prevalence of colonization; at 2 years, none of the children had positive cultures.[316] However, in one large study of pediatric patients with chronic respiratory disease, 8.8 percent carried *U. parvum* and 2.8 percent carried *U. urealyticum* in their respiratory tract.[778]

During prepubertal childhood, *Ureaplasma* spp. are recovered only rarely from urine or genital specimens.[314,563] After puberty, colonization is a common occurrence and is primarily the result of sexual contact.[643,645,647] Colonization in adults is related directly to sexual activity. In population studies, *Ureaplasma* spp. rarely are isolated from persons with no sexual experience, but they occur in approximately 50 percent of men and 75 percent of women for whom sexual intercourse with three or more partners is reported.

Clinical Manifestations

Because *Ureaplasma* can be recovered with considerable frequency from the throat, eyes, and genitourinary tract of babies and from the genitourinary tract of postpubertal males and females who are well, establishing cause-and-effect relationships in disease frequently has been difficult. Studies suggest the following disease associations with *Ureaplasma* in human genitourinary and reproductive disease: good to strong association with nongonococcal urethritis, prostatitis, and urethral syndrome; moderate association with epididymitis, involuntary infertility, repeated spontaneous abortion and stillbirth, chorioamnionitis, and low birth-weight; weak association with urinary calculi, pyelonephritis, Reiter disease, and pelvic inflammatory disease; and no association with Bartholin gland abscess, vaginitis, cervicitis, postabortal fever, and postpartum fever.‡

Adverse Pregnancy Outcomes and Infertility

There has been much debate regarding genital mycoplasmas and whether they play a role in spontaneous abortion and premature labor, although supporting evidence is growing.[269,1014] The Alabama Preterm Birth Study in 2008[354] examined umbilical cord blood cultures for genital mycoplasmas in very preterm newborn neonates (i.e., 23 to 32 weeks' gestation). They found *U. urealyticum*, *M. hominis*, or both in 23 percent of the samples and more commonly in infants of nonwhite mothers (27.9% vs. 16.8%, $p = .016$), mothers younger than 20 years of age, those having a spontaneous rather than an indicated preterm delivery (34.7% vs. 3.2%, $p = .0001$), and those delivering at an earlier gestational age. Infants with positive cultures were more likely to have had intrauterine infection and inflammation, as shown by positive placental cultures, elevated cord blood IL-6 levels, and placental histology. Positive growth for these genital mycobacteria in cord blood also was associated with systemic inflammatory response syndrome (41.3% vs. 25.7%, $p = .007$). No significant difference between groups was found for intraventricular hemorrhage or death. Romero and Garite[824] commented on particularly significant findings from this study, including that genital mycoplasmas caused bacteremia in 1/4 of very preterm newborns, most commonly *U. urealyticum*, although a large number (i.e., 22% of those with positive umbilical blood cultures) had simultaneous colonization with *M. hominis*. They raise the question of whether these organisms should be screened for in routine prenatal and perinatal care, and whether standard neonatal sepsis antibiotic regimens should be adjusted to cover them. Waites and associates[1019] wrote a comprehensive review of recent literature trying to support a link between genital mycoplasmas and adverse outcomes. Comparisons of recent findings in prophylactic antibiotic use to forestall these outcomes, however, were inconclusive, possibly as a result of the varied methods used.

Genital mycoplasmas can invade the upper genital tract and cause inflammation, and this has been proposed as a potential cause of infertility.[380,436] In addition, some *Mycoplasma* spp. can bind and affect sperm; infertility in men has been associated with these infections.[232,339,839] These topics will not be discussed further because they are outside the scope of this text's pediatric focus.

Nongonococcal Urethritis

Nongonococcal urethritis occurs more commonly than gonococcal urethritis in men in most developed countries (Tully J G. Personal communication. December 1, 1991).[391,451,642] Approximately 40 percent of cases of nongonococcal urethritis are caused by *Chlamydia trachomatis*, and 20 to 30 percent are the result of *Ureaplasma* infection.* Clinical differentiation of disease caused by *C. trachomatis* and *Ureaplasma* has not been studied, but nongonococcal and gonococcal urethritis have been evaluated comparatively.[388,451,563,1004]

*References 94, 95, 206, 413, 648, 855.

The incubation period in nongonococcal urethritis is relatively long, with most cases occurring 10 to 20 days after exposure, whereas with gonorrhea the period is shorter, usually less than 1 week.[388] The onset of symptoms in nongonococcal urethritis is generally more gradual than that associated with gonorrhea. Virtually all men with gonorrhea have a urethral discharge, and most have both discharge and dysuria. In contrast, Jacobs and Kraus[451] found that only 38 percent of men with nongonococcal urethritis had both dysuria and discharge. In the same study, 15 percent of patients with nongonococcal urethritis had only dysuria, whereas only 2 percent of those with gonococcal urethritis had a similar problem. On examination, Handsfield[388] found the discharge in nongonococcal urethritis to be purulent in 36 percent of his cases, nonpurulent in 9 percent, and of an intermediate character in the remaining 55 percent. In contrast, 73 percent of patients with gonorrhea had a purulent discharge, 27 percent had an intermediate discharge, and none had a nonpurulent discharge. Because of the more gradual onset and the usually less severe symptoms, patients with nongonococcal urethritis are less prompt in seeking medical care than those with gonorrhea. Jacobs and Kraus[451] found that 76 percent of patients with discharge and gonococcal infection came to the clinic within 4 days of onset, whereas only 43 percent of patients with similar nongonococcal urethritis visited the clinic within 4 days of disease onset. Without treatment, nongonococcal urethritis symptoms subside gradually in some patients during a 1- to 3-month period.[763]

After penicillin, ampicillin, or spectinomycin treatment of men with urethral gonorrhea, urethritis recurs (postgonococcal urethritis) in many patients.[414] Studies of postgonococcal urethritis indicate an etiologic role for *C. trachomatis;* genital mycoplasmas are probably responsible for some cases,[764] especially as persistent urethritis after doxycycline treatment also has been reported.[1045]

A 7½-year-old sexually inactive boy with recurrent urethritis associated with *U. urealyticum* infection has been described.[874]

Other Infections

Ureaplasma has also been associated with postoperative mediastinitis in adults.[335,340,386]

Disease in the Neonate

Transmission. Vertical transmission of *Ureaplasma* spp. and *M. hominis* from a colonized mother to her newborn occurs in utero or during delivery.[6,16,362,842,1014] The relative frequency of occurrence at each time point is not fully known. Acquisition of mycoplasmas by newborns can occur at the time of delivery through contact with a colonized birth canal, but they also have been found on the mucosal surfaces of newborns delivered by cesarean section performed before the onset of labor and rupture of amniotic membranes.[844,940] In utero transmission occurs either transplacentally by the hematogenous route or via an ascending intrauterine infection from a colonized maternal genital tract. Mycoplasmas have been isolated from maternal blood at the time of delivery and

from umbilical cord blood, amniotic fluid, endometrium, chorioamnion, placenta, and aborted fetal tissue. Specific IgM antibody responses have been detected in neonatal serum. Postpartum or nosocomial transmission probably occurs, but definitive proof is lacking. The idea was suggested by the finding of ureaplasmal colonization in infants at 3 to 4 weeks of age who were not previously shown to be colonized with *Ureaplasma* spp. while in a neonatal intensive care unit (NICU).[844]

The rate of vertical transmission of *Ureaplasma* spp. ranges from 0.9 to 55 percent in full-term infants and 8.5 to 58 percent in preterm infants, depending on the number and type of mucosal surfaces sampled.[16,179,751,842-844,940] *M. hominis* has been isolated from the nasopharyngeal aspirates and gastric secretions of 30 to 42 percent[178,179] and 8 percent,[362] respectively, of infants born to colonized mothers. The rate of vertical transmission of *Ureaplasma* spp. is not affected by the method of delivery or the duration of time after rupture of membranes. Vertical transmission is increased significantly in the presence of chorioamnionitis and intraamniotic infection.[235,888] Colonization of newborn infants increases with decreasing gestational age and birth-weight[10] and is highest in infants weighing less than 1000 g at birth.[844] Female newborns are more likely than males to be colonized with *Ureaplasma* because the vagina is a common site of colonization.[315,843]

Colonization with *Ureaplasma* persists through early infancy; 68, 33, and 37 percent of full-term newborns colonized in the throat, eye, and vagina, respectively, are still colonized at 3 months of age.[940] However, most of them lose colonization by the time they reach 2 years of age.[315] Among preterm infants, 65 percent remain colonized at the time of discharge from the NICU or at 28 days of life.[844] Overall, the prevalence of ureaplasmal colonization varies from 2 to 86 percent among infants admitted to NICUs, and as many as 14 to 41 percent of infants have endotracheal aspirate cultures positive for *Ureaplasma* spp.*

Clinical Manifestations

The role of *Ureaplasma* spp. in neonatal disease continues to be investigated and defined. *M. hominis* and *Ureaplasma* spp. have been recovered from the lungs, brain, heart, and viscera of aborted fetuses and stillborn infants, with histologic findings of bronchopneumonia present in the lungs.[614,943] *Ureaplasma* spp. were isolated from blood in as many as 34 percent of infants younger than 34 weeks' gestational age.[758] Twenty-six percent of preterm infants had positive endotracheal aspirate cultures for *Ureaplasma* spp. in one study.[135] Genital mycoplasmas also have been isolated from the blood, urine, CSF, and lung tissue of infants with clinical signs of infection. These organisms frequently colonize the mucosal surfaces of newborns,[513,844] and ascribing disease often is difficult. However, isolation from normally sterile body fluids in symptomatic infants has led to the recognition that these organisms are neonatal pathogens.

*References 217, 254, 400, 444, 759, 842.

Chorioamnionitis

In a study of 249 puerperal women and their babies, Shurin and colleagues[888] noted on histologic examination of the placentas that *Ureaplasma* spp. were recovered from 37.5 percent of babies whose placentas showed chorioamnionitis and from only 19 percent of those with normal placentas. In this study, no adverse effects could be attributed to either the placental lesions or colonization of the babies. Another group found that *U. urealyticum* and *M. hominis* in the umbilical cord was associated with funisitis, but the presence of these organisms in the placenta, tracheal aspirate, or gastric fluid of preterm infants did not show a significant difference in the presence of chorioamnionitis in the mother or chronic lung disease in the baby.[260] Caspi and associates[128] reported a 32-year-old woman with amnionitis in whom *Ureaplasma* was recovered from blood. After delivery, the same organism was recovered from the blood of one of the twin infants.

Pneumonia

Fatal neonatal pneumonia in a term infant was documented by isolation of *Ureaplasma* from lung tissue at autopsy, with demonstrated elevated serum IgG and IgM titers to the organism.[801] Afebrile pneumonitis was reported in infants younger than 3 months of age.[918] Pneumonia and persistent pulmonary hypertension were documented in three infants from whom *Ureaplasma* spp. were isolated from blood, endotracheal aspirates, pleural fluid, or lung tissue (or any combination of these sites) at autopsy.[1014] Cultrera and colleagues[214] reported finding an association between colonization of the lower respiratory tract by *Ureaplasma* spp., particularly by *U. parvum* in preterm newborns, and respiratory distress syndrome. The potential role of *Ureaplasma* in neonatal pneumonia[116,332,350,769] has been strengthened by demonstration of histologic evidence of pneumonia in the lungs of newborn mice and premature baboons; ureaplasmal isolates were obtained from the pleural fluid, lung biopsy specimens, and lung tissue of these experimental pneumonia models.[132,829,1021] Crouse and associates[209] demonstrated that pneumonia is produced in newborn mice, but significantly less often in mice older than 14 days, and is potentiated by oxygen therapy. *Ureaplasma* spp. have been shown to induce ciliostasis and mucosal lesions in human fetal tracheal organ cultures.[132] In addition, *Ureaplasma* can induce the production of alveolar macrophage proinflammatory cytokines in vitro,[577] and both *Ureaplasma* spp. and *M. hominis* stimulate the production of tumor necrosis factor (TNF)-α and inducible nitric oxide synthase from murine macrophages.[210] Viscardi and colleagues[1001] developed the first juvenile mouse model of *Ureaplasma* pneumonia. Their data suggest that *Ureaplasma* alone may cause limited inflammation and minimal tissue injury in the early phase of infection but may promote a mild chronic inflammatory response in the later phase of infection (days 14 to 28), similar to the process that occurs in human newborns.

Chronic Lung Disease

Isolation of *Ureaplasma* spp. from endotracheal secretions, the nasopharynx, the throat, or gastric aspirates (or any combination of these sites) has been associated with chronic lung disease of prematurity. Development of chronic lung disease was described in low-birth-weight infants whose respiratory tracts were colonized with *Ureaplasma* spp. in the first week of life.*

The results from a meta-analysis performed by Wang and colleagues[1024] involving 17 publications supported a significant association between ureaplasmal colonization and the subsequent development of chronic lung disease. Crouse and associates[211] noted that infants who weighed 1250 g or less at birth, had respiratory tract disease, and were colonized with *Ureaplasma* spp. in their tracheal secretions were more likely to have radiographic evidence of more severe pulmonary disease than were infants who were not colonized. Similar findings were made by Honma and coworkers,[416] who noted that infants younger than 32 weeks' gestational age with elevated white blood cell counts and *U. urealyticum* colonization were more likely to develop infection-related chronic lung disease. These findings were not supported by studies by Cordero and colleagues,[201] who did not detect any specific radiographic abnormalities in 183 infants with a birth-weight of 1250 g or less and who had endotracheal colonization with *Ureaplasma* spp., gram-negative cocci, or gram-negative bacilli. However, Ollikainen and associates[755] found that preterm infants colonized with Ureaplasma spp. had higher leukocyte counts on the first 2 days of life and that they required high-frequency oscillatory ventilation more often than those not colonized. In addition, the isolation by Walsh and colleagues[1022] of *Ureaplasma* spp. from the lungs of infants with chronic lung disease implies an invasive bacterial process as part of the pathogenesis of lung injury. In a retrospective study of 60 ventilated babies born at less than 30 weeks' gestation, 25 of whom were *Ureaplasma* culture–positive, Theilen and associates[968] found that the ventilated babies with *Ureaplasma* in their tracheal secretions had a clinical and radiologic course different from that of the infants who were culture-negative. Specifically, they had less acute lung disease but an earlier onset of chronic lung disease.

In contrast to these studies, Heggie and colleagues,[400] Da Silva and associates,[217] and Couroucli and colleagues[207] found no association between *Ureaplasma* and the development of bronchopulmonary dysplasia (BPD). Bowman and colleagues[96] used erythromycin to treat infants with extremely low birth-weight infants colonized with *Ureaplasma* and found no association between the initial colonization and the development of chronic lung disease. They also called attention to the fact that in the study by Heggie and coworkers,[400] a substantial proportion of the colonized infants were treated with erythromycin, which might explain the lack of an association between colonization and subsequent chronic lung disease. In 1997, Van Waarde and associates[993] noted that preterm infants who were at the highest risk for the development of chronic lung disease (i.e., those with the lowest gestational age and birth-weight) also were the ones most likely to be colonized with *Ureaplasma* spp. Castro-Alcaraz and coworkers[139] found that a persistently positive colonization pattern, which accounted for 45 percent of the *Ureaplasma*-positive infants, was associated with a significantly increased risk for the development of chronic lung disease.

One theory suggests that *Ureaplasma* is not the primary cause of BPD but might be the cause of undetected pneumonia.[133] This pneumonia results in an increased requirement for supplemental oxygen, and BPD is the result of oxygen toxicity caused by the supplemental oxygen therapy. Viscardi and associates,[1000] using the preterm baboon model, suggested that a prolonged proinflammatory response initiated by intrauterine *Ureaplasma* infection contributed to the early development of fibrosis and altered developmental signaling in the immature lung.

The possibility that ureaplasmal colonization of the respiratory tract induces an inflammatory response without direct pulmonary invasion and infection cannot be excluded.[375,608] It has been supported by the finding of elevated levels of TNF-α, IL-6, IL-8, and monocyte chemoattractant protein–1 (MCP-1) in the tracheal secretions of colonized infants,[42,132,376,624,925] as well as by elevated white blood cell counts and eosinophilia in infants whose respiratory tract is colonized by *Ureaplasma* spp.[753,755,771] The contribution of *U. urealyticum* and *U. parvum* was evaluated by Heggie and colleagues.[400] Both species colonized preterm infants with a birth-weight of less than 1500 g; however, no association was seen between endotracheal colonization with either species and the development of chronic lung disease. In a study performed by Katz and colleagues,[487] *U. parvum* was detected more often than *U. urealyticum*, but the researchers found no significant difference or trend in the prevalence of either species between infants with or without BPD. Similarly, the Alabama Preterm Birth Study showed no association between *Ureaplasma* infection and respiratory distress syndrome (RDS).[354] However, Cultrera and associates[214] did find a strong association in preterm infants of RDS development and colonization, especially with *U. parvum*.

In a meta-analysis, Schelonka and colleagues[859] reviewed 36 articles in which cohorts of neonates were screened for the presence of *Ureaplasma* by culture with or without PCR and monitored prospectively for the development of BPD. They concluded that colonization with *Ureaplasma* was associated with higher reported rates of BPD. However, the greatest reported effect was seen in the small studies, and, therefore, reporting bias may be partially responsible for the higher rates of BPD in colonized infants. The Alabama study could also find no significant association with BPD when adjusted for maternal race, infant gestational age, and gender.[354]

Central Nervous System Infections

Both *Ureaplasma* spp. and *M. hominis* have been isolated from the CSF of both full-term and preterm infants.*

*References 3, 15, 17, 27, 45, 56, 94, 114, 122, 127, 133, 138, 155, 188, 190, 191, 202, 220, 259, 264, 416, 532, 779.

*References 20, 119, 336, 346, 394, 409, 508, 629, 651, 728, 873, 889, 919, 990, 1016, 1018.

The repeated isolation of these organisms from the CSF of predominantly preterm infants with suspected meningitis and their association with a CSF pleocytosis consisting of polymorphonuclear or mononuclear cells, hypoglycorrhachia, and elevated protein content support their role in causing neonatal meningitis. Waites and colleagues[1015] noted hemiplegia, hydrocephalus, and developmental delay in survivors.

Isolation of *Ureaplasma* spp. from the CSF of preterm infants also has been associated with severe intraventricular hemorrhage.[4,757,1017] However, Likitnukul and associates[578] cultured the CSF and blood of 203 infants with suspected sepsis and failed to isolate *Ureaplasma* spp. Primarily in full-term infants, isolation of *Ureaplasma* spp. and *M. hominis* often has been associated with minimal if any CSF abnormalities, and these infants have done well without receiving specific antimicrobial therapy.[401,728,859,990,1016] In such instances, the presence of these organisms remains of unclear clinical significance, and their role in producing disease is questionable.

Other Infections

Nonimmune hydrops fetalis was reported in a newborn at 32 weeks' gestation in whom *U. urealyticum* was isolated from bronchial secretions and lung and brain tissue at autopsy.[756] Osteomyelitis of the femur was associated with isolation of *Ureaplasma* from the blood of a preterm infant.[349] *Ureaplasma* was recovered from a scalp abscess at the site of an internal fetal electrode monitor.[387]

Differential Diagnosis

In clinical practice the most important differential consideration is between gonococcal infection and nongonococcal urethritis. Although the symptoms of the two illnesses are frequently different, sufficient overlap exists to render arriving at a specific diagnosis without laboratory aid hazardous. Microscopic examination of a urethral specimen is essential. In most instances the observation of gram-negative cell-associated diplococci on Gram stain is sufficient for a diagnosis of *Neisseria gonorrhoeae* infection. When smears reveal polymorphonuclear neutrophils without organisms suggestive of gonococci, a specific bacterial culture should be performed. Because infection with multiple agents occurs commonly and postgonococcal urethritis is a frequent problem, thorough investigation of initial illnesses in adolescents with cultures for bacteria, *Chlamydia*, and *Ureaplasma* is advised.

Because of the frequent colonization of newborn infants with mycoplasmas, an etiologic role for these agents cannot be supported by detection of organisms on mucosal surfaces only. However, isolation from normally sterile sites would support further workup and possibly treatment.

MYCOPLASMA HOMINIS

Properties

Three basic morphologic forms of *M. hominis* have been observed by phase-contrast microscopy: coccoidal cells 30 to 80 nm in diameter, diploforms and filamentous forms with a thickness of 30 to 40 nm, and forms with variable lengths reaching 40 μm or more.[90,102,104,237] Bredt[103] studied newly isolated strains and noted that coccoid forms and ring- or disk-shaped cells were predominant; with some strains, filamentous forms of variable length also were noted. Multiplication occurs by binary fission, by fragmentation of filaments and rings, and by budding.[90,820]

Anderson and Barile[22] studied the ultrastructure of *M. hominis* and noted considerable variability in internal components. In some cells, ribosome-like granules in the cytoplasm and a more central area of netlike strands were present, suggestive of a nucleus. Other cells had only irregular densities within the cytoplasm. In some instances, dense cytoplasmic bodies were observed; in other cells, vacuoles were seen.

On *Mycoplasma* agar, M. *hominis* colonies are approximately 200 to 300 μm in diameter and have the typical mycoplasmal "fried egg" appearance.[958] *M. hominis* grows on ordinary blood agar and produces pinpoint nonhemolytic colonies. It metabolizes arginine to ammonia, so arginine-supplemented liquid medium with a pH indicator (phenol red) can be used for primary isolation. *M. hominis* can be identified specifically and differentiated from other human mycoplasmas that metabolize arginine by growth inhibition by specific antibody.

M. hominis has two cytoadhesins that are membrane proteins; they allow attachment to cells of the urogenital tract and to trichomonas.[405] Attachment is to sulfated glycolipids of the host cells.[760]

Epidemiology

M. hominis colonizes the urogenital tracts of sexually active adults,* with the rate of carriage in women estimated to be 20 to 50 percent.[99,649,957] One study study that found an association between pregnancy and *Ureaplasma* colonization noted only minimal rates of *M. hominis* carriage and no significant difference in rate in pregnancy.[38] The rest of its epidemiology follows the same characteristics as those listed for the *Ureaplasma* spp. Similarly, the simple presence of *M. hominis* in the lower genital tract during pregnancy is not predictive of adverse outcomes[137,270,1013] and has a controversial role in causing spontaneous abortion and preterm delivery.[269,1012] Like the *Ureaplasma* spp., it can invade the upper genital tract. *M. hominis* has been shown to be a cause of pelvic inflammatory disease, postpartum septicemia, and endometritis,[132,494,650,732,787] and it has been associated with surgical wound infection after cesarean delivery.[526,611,819] It can be recovered from the oral cavity of 1 to 5 percent of normal adults.[912] In one large study it was found in the respiratory tract of 4.7 percent of pediatric patients with chronic respiratory tract disease.[778]

M. hominis has been identified inside *Trichomonas vaginalis*, where it is believed to play a symbiotic role.[233,694] *T. vaginalis* strains harboring *M. hominis* were found to have increased virulence behavior.[994] Conflicting reports exist of metronidazole resistance being conferred by *M. hominis*.[120,1052]

*References 320, 643, 645, 647-649, 957, 1012.

Clinical Manifestations

Studies suggest the following disease associations with *M. hominis* in human genitourinary and reproductive diseases: good to strong association with pyelonephritis, pelvic inflammatory disease, postabortal fever, and postpartum fever; moderate association with prostatitis, vaginitis, and cervicitis; weak association with Bartholin's gland abscess and involuntary infertility[339,506]; and no association with nongonococcal urethritis epididymitis, urinary calculi, Reiter disease, urethral syndrome, repeated spontaneous abortion and stillbirth, and chorioamnionitis.* With the exception of pelvic inflammatory disease and complications of pregnancy, which occur in adolescents, the other disease associations reported do not involve pediatric patients.

M. hominis has been recovered on two occasions from the CSF of a 2½-year-old girl with a ventriculoperitoneal shunt.[1015] Because she had no complications from the infection and only minimal CSF inflammation, no treatment was initiated. Three months later, the organism could not be isolated from CSF and the child was doing well.

In volunteer studies in adults, researchers found that *M. hominis* could produce exudative pharyngitis.[149] Moffet and associates[685] isolated *M. hominis* from the throat of 1/174 infants and children with pharyngitis but made no similar isolation from a control group of children without pharyngitis. Neu and Ellner[733] recovered *M. hominis* from the throat of 1 child in a group of 56 with exudative pharyngitis. Other *M. hominis* infections include septicemia in a 10-month-old burned infant,[221] chronic multifocal osteomyelitis in an 8-year-old child,[432] septicemia after heart surgery in a 5-year-old girl,[220] severe pneumonia and pericarditis in a healthy 15-year-old female,[777] and exudative vaginitis in a 10-year-old girl.[1015] In one study, 10 patients with sickle-cell disease were found to have acute chest syndrome in association with *M. hominis* recovery from sputum or bronchoscopy specimens.[734] A 4-year-old girl was found to have *M. hominis* endocarditis after biventricular repair of her congenital heart defect.[238] Surgical wound infections have been due to *M. hominis* infections.[536,818]

In adult patients, the following clinical manifestations have been caused by *M. hominis:* mediastinitis,[335,639,709] endocarditis,[288,422,452] isolated pericarditis in a lung transplant recipient,[679] pneumonia in a previously healthy man,[836] ICU-acquired infection in seven critically ill men,[333] soft tissue and cavity infections at surgical sites,[123,526,676,1054] parapharyngeal abscess after Epstein-Barr virus infection,[495] septic arthritis in a patient with hypogammaglobulinemia,[851] brain abscess,[14,423,541,542,1068] and bacteremia in a patient with multiple injuries.[378]

Disease in the Neonate

Infants become colonized during passage through the birth canal, but such colonization tends to not persist. In a recent study of 208 women at delivery, *M. hominis* was recovered from cervicovaginal specimens in 11 percent and the gastric secretions of 1 percent of newborns.[362] In prepubertal children, *M. hominis* only rarely is recovered from urine or genital specimens.

M. hominis also has been associated with neonatal pneumonia,[988] septicemia,[132] and meningitis in premature infants.[399,1036] A review by Hata and colleagues[394] associated poor outcomes with delayed or infective initial therapy of *M. hominis* meningitis, and presented a case in a premature infant that was successfully treated with moxifloxacin, promoting fourth-generation fluoroquinolones as an alternative treatment. A case was found of an infant sustaining birth-related eye injury who subsequently developed multiple subdural empyemas caused by *M. hominis.*[174] Other systemic presentations include brain and scalp abscesses, ventriculitis, submandibular adenitis, abscesses of subcutaneous tissue, pericarditis, and conjunctivitis.[1,351,471,673,794,835]

Differential Diagnosis

Illness caused by *M. hominis* infection rarely occurs in children. This organism should be considered an etiologic possibility in wound infections and a variety of illnesses in which routine cultures are negative. The possibility of *M. hominis* as an etiologic agent also should be considered in adolescent girls with urethritis or pelvic inflammatory disease.

MYCOPLASMA GENITALIUM

Properties

A thorough review by Taylor-Robinson and Jensen[956] summarizes the recent characterization of *M. genitalium*. It is a pleomorphic organism most often found with a tapered end, giving it a flask or bottle shape. It has a length of 0.6 to 0.7 μm and a diameter of 0.3 to 0.4 μm at the broadest part and 0.06 to 0.07 μm at the tip. As in other mycoplasmas, the terminal rodlike structure is believed to play a role in motility, cytoadherence, and binary fission.

Colonies have the typical "fried egg" morphology on solid media. Growth is suppressed on *Mycoplasma* media containing thallous acetate, which is normally used to prevent bacterial contamination. In media containing phenol red and glucose, *M. genitalium* metabolism can be detected by a color change from red to yellow. *M. genitalium* does not metabolize arginine or urea.

M. pneumoniae is closely related to *M. genitalium* and is believed to contain all of the latter's open reading frames within its genome.[408] Because of similarities in their antigens, cross reactivity between the two can occur in serologic testing. The genome of *M. genitalium* (580 kb) is much smaller, however, which necessitates efficiency. Rather than encode gene regulators, it is believed to rely on DNA supercoiling,[245] antisense RNA,[593] and environmental signals such as osmotic stress[1067] and temperature[707] to modify transciption. It is also able to produce unlimited variants of its genes through homologous recombination within its own

*References 87, 112, 134, 265, 266, 343, 379, 543, 767, 768, 827, 884, 924, 958, 981, 982.

genome and through gene exchange between different clones.[443,610]

Epidemiology

Over recent years, *M. genitalium* has become recognized as an STI that causes nongonococcal urethritis in men and is strongly implicated in several inflammatory reproductive tract syndromes in women, including cervicitis, endometritis, pelvic inflammatory disease, and infertility in both men and women.[82,339,382,620,655] A comprehensive review of the literature by McGowin and associates[656] found a worldwide incidence of 7.3 percent and 2.0 percent, in high- and low-risk female populations, respectively. Rates of infection are not associated with ethnicity, gender, isolation site, or previous pregnancies in women,[554,826] but have occasionally been shown to be associated with younger age, thought to be related to sexual promiscuity and risky behavior.[470,684] *M. genitalium* infection was shown to be significantly reduced in circumcised versus uncircumcised men (8.2% and 13.4%, respectively).[663] Studies in the adult general population abroad have shown an asymptomatic carrier rate of 0.3 percent in Korea,[506] 0.6 percent in the United Kingdom,[826] and 1 percent in Japan,[945] whereas in a study by the University of Illinois, investigators reported that of the 52 male patients with *M. genitalium* in their patient population in Kenya (9.9% prevalence), all but one were asymptomatic.[663]

In addition, multiple studies have shown elevated coinfection rates of *M. genitalium* with HIV.[338,470,640,720] It is unclear whether this relationship is pathologically significant or merely represents the elevated risk for multiple infections in people with high-risk sexual activity.[619,956] Reports are conflicting about whether infection with *M. genitalium* is associated with increased vaginal HIV shedding.[338,623,656]

The organism also has been recovered from the respiratory tract of patients with pneumonia who were participating in an *M. pneumoniae* vaccine trial.[52] Patel and colleagues[778] found colonies in the lower respiratory tract of a large pediatric population with chronic respiratory disease to be 9.8 percent.

Clinical Manifestations

The role of *M. genitalium* as a sexually transmitted pathogen was initially unclear and required careful characterization, including studies of disease in experimentally infected chimpanzees.[958,978,982] With the use of PCR, Jensen and associates[463] presented evidence suggesting a causative role in some cases of nongonococcal urethritis. *M. genitalium* is an emerging STI[622] and a cause of mucopurulent cervicitis in women[621] and nongonococcal urethritis in men.[664]

M. genitalium has been recovered from pediatric patients with pneumonia and chronic respiratory disease.[52,778] Respiratory colonization has been shown to occur during neonatal passage though the birth canal for other mycoplasmas. Hematogenous spread of *M. genitalium* is also possible and has been postulated as the mechanism for cases of arthritis with this organism.[956,979]

Differential Diagnosis

M. genitalium presents most commonly as an STI causing pathology in the lower genital tracts of both men and women and a possible role in upper tract inflammation. It should be considered in the workup of adolescents with urethritis or pelvic inflammatory disease.

MYCOPLASMA FERMENTANS

M. fermentans originally was isolated from the genital tract of men and women over 50 years ago, but it has not been established as a cause of genitourinary disease.[831,953,978] This organism has been isolated from the blood of leukemia patients, from the joint fluid of patients with arthritis, and from the blood and urine of patients with acquired immunodeficiency syndrome (AIDS).* *M. fermentans* has been identified by PCR in the peripheral blood mononuclear cells and lymph nodes of HIV-infected patients.[395,486,533,850] The organism also has been recovered from the blood of homosexual men without HIV infection.[486,533,613] *M. fermentans* has been identified in the blood and synovial fluid of patients with inflammatory arthritic diseases, including rheumatoid arthritis.[345,469,910]

MYCOPLASMA PENETRANS

M. penetrans is a relatively newly recognized species isolated from the urogenital tract of patients with AIDS.[594,595] In a seroprevalence study, Wang and associates[1028] found that 35.4 percent of HIV-infected patients had antibody versus only 0.4 percent of HIV-seronegative subjects. They subsequently noted a high prevalence of antibody to *M. penetrans* in the sera of homosexual men but not in the sera of other HIV transmission groups.[1029] In a more recent study, Grau and colleagues[364] found that 18.2 percent of HIV-infected patients had antibody to *M. penetrans*, whereas only 1.3 percent of HIV-seronegative persons had antibody. *M. penetrans* antibody seroprevalence increased with progression of HIV-associated disease, and it was associated predominantly with homosexual practices in the HIV-infected patients. No pediatric data relating to *M. penetrans* seroprevalence are available.

DIAGNOSIS OF CONGENITAL MYCOPLASMAS

M. hominis, *U. urealyticum*, and *U. parvum* are ubiquitous in the genital tracts of normal persons and frequent colonizers of mucosal surfaces in infants; therefore, assigning causation of disease based on isolation is difficult. *M. genitalium* is becoming more widely recognized as an STI, and its identification in cases of urethritis carries more suspicion. Culture or PCR for mycoplasmas may be warranted in nongonoccocal urethritis when smears reveal polymorphonuclear neutrophils without

*References 53, 85, 630, 690, 705, 1034, 1046.

organisms suggestive of gonococci. Isolation of these species from a normally sterile site or suppurative focus warrants further investigation, especially in newborns and others with weakened immune systems. The clinical significance of isolation of genital mycoplasmas from urine obtained by suprapubic bladder aspiration in infants remains to be determined.[579] In such instances, analysis of urinary sediment has been normal.

Because of their fastidious growth, these species cannot be identified by routine bacteriologic culture methods, and therefore specific culture for *Mycoplasma* must be requested. Genital mycoplasmas may be isolated on special broth and solid media that are available commercially. Shepard 10B broth and A8 agar have been used successfully for cultivation.[132] A recent study comparing different culture specimens found that urethral swabs were more accurate (specificity, 99.9%; positive predictive value [PPV], 99.6%) than vaginal swabs (specificity 95.1%; PPV, 67%) or urine cultures (specificity, 96%; PPV, 75%) for detecting *M. hominis* in women with lower urinary tract symptoms, with similar numbers for *U. urealyticum*.[431]

Cassell and colleagues[131,132] recommended that mucosal specimens be obtained with a Dacron or calcium alginate swab and be placed in a specific mycoplasmal transport medium such as Shepard 10B broth. Specimens should be refrigerated at 4° C (39.2° F) until they are transported to the laboratory and should be protected from drying. Alternatively, specimens in appropriate transport media can be frozen at −70° C (−94° F) because mycoplasmas are stable for long periods under these conditions. Specimens should be diluted serially in 10B broth to at least 10^{-3} (preferably to 10^{-5}) to overcome any potential inhibitory substances or metabolites, and an aliquot of the original sample and dilution should be plated directly onto A8 agar. Body fluids (e.g., blood, CSF, and pleural fluid) should be inoculated into 10B broth in an approximate 1 : 10 ratio (usually 0.1 mL fluid/0.9 mL 10B broth). Blood should be collected free of anticoagulants. Broth cultures and agar plates are incubated under 95 percent nitrogen and 5 percent carbon dioxide. Cultures generally become positive within 2 to 5 days. The presence of mycoplasmal growth in 10B medium is indicated by a change in color from yellow to pink, which is caused by an alkaline shift in the media as a result of either the urease activity of ureaplasmas or arginine hydrolysis by other *Mycoplasma* spp. Growth of mycoplasmas in broth culture, as indicated by a change in color, should be confirmed by inoculation of a broth specimen onto A8 agar. Characteristic colonies can be identified readily on A8 agar after 24 to 72 hours of incubation.

Serologic tests have been used to measure antibody to genital mycoplasmas. Such tests include the metabolic inhibition assay, enzyme-linked immunosorbent assay, mycoplasmacidal test, indirect hemagglutination, indirect immunofluorescence, and IgG and IgM immunoblotting.[132,236,330,802] Because of the presence of maternal antibodies, as well as their own poorly functional immune system, use of these tests for establishing the diagnosis of mycoplasmal infection in infants remains problematic and is not well established. In these cases, diagnosis should rely on culture results and/or PCR.

PCR assays have become commercially available over recent years for detecting genital mycoplasmas.[86,821,929,1063] Comparison studies show that PCR is a more rapid and sensitive method of detection for genital mycoplasmas than culture. On endotracheal secretions, Blanchard and associates[86] reported finding a sensitivity of 100 percent and a specificity of 99 percent for *Ureaplasma* spp.

PCR assays involving the urease gene, 16S RNA genes, and multiple-banded antigen genes have been used to detect *Ureaplasma* spp.* PCR detection of 16S rRNA and ribosomal DNA targets of *M. hominis*[6,363,605] and the 23S rRNA[460] and 16S rRNA[678] from *M. genitalium* are available. Assays now exist that can screen for multiple *Mycoplasma*-related species simultaneously, using fluorescence polarization,[48] PCR-RFLPs,[678] multiplex PCR[658-660,841] and oligonucleotide microarrays.[453] Ultimately, these methods may aid in identifying colonized or infected infants more readily (results available in 1 day) and reliably, given the fastidious nature of these organisms and the scarcity of microbiology laboratories that routinely perform mycoplasmal culture.

OTHER *MYCOPLASMA* SPECIES AND *MYCOPLASMA* RELATIONSHIPS

Mycoplasma Salivarium

M. salivarium is part of the normal human oral flora and has been thought to occasionally play a role in oral and periodontal infections[1032]; however, it has rarely been associated with disease in other sites of the body. Examples include arthritic joints such as the knee of a 39-year-old-woman with hypogammaglobulinemia,[906] the knees of rheumatoid arthritis patients,[469] the synovial fluid of patients (including a 15- and 16-year-old girl) with temperomandibular joint disorders,[1032] a submasseteric abscess in an 84-year-old woman,[373] and an empyema in a 39-year-old man with laryngeal cancer.[49] The organism was also found in the polymicrobial biofilm of an occluded biliary stent in a 71-year-old man with liver cirrhosis.[406]

Mycoplasma Pirum

M. pirum originally was recovered from eukaryotic cell cultures, and its origin was traced to a human tumor cell line.[15,230,557] It has been recovered more recently from primary lymphocyte cells in patients with AIDS.[85]

Zoonotic *Mycoplasma*

Mycoplasma spp. have been identified that infect a wide variety of birds, reptiles, fish, and mammals. Human infection with these species is rare but can occur when there is close contact, such as in veterinary medicine, animal training, hunting, fishing, and agriculture. There have been reports of fishermen with open hand wounds or bites catching *Mycoplasma phocacerebrale* from seals. Commonly referred to as "seal finger," this disease

*References 6, 7, 21, 86, 156, 173, 216, 605, 608, 731, 821, 861, 963, 1062.

involves cellulitis of the affected area with eventual joint involvement if not treated.[43,455,1043] Hemotropic mycoplasmas (also known as "hemoplasmas") cause hemolytic anemia in many domestic and farm animals, and cases have been described of humans being infected through arthropod vectors associated with pigs, sheep, cattle, dogs, and cats,[92,246,429,939,1034,1065] and in one case a novel hemoplasma with no identified origin was found in a 60-year-old woman.[927] Coinfections with *Bartonella* spp. are not uncommon. Outbreaks of hemoplasmas in China have been described, including a high prevalence of congenital infection with severe disease.[429,1056]

Acquired Immunodeficiency Syndrome–Associated Mycoplasmal Infections

The frequent identification of *M. fermentans*, *M. pirum*, and *M. penetrans* infections in HIV-infected patients led to the consideration that they may function as cofactors in the progression of HIV infection and immunodeficiency.[85,530,419,690] Although these mycoplasmas have the capacity to invade cells and to be potent immunomodulators, their pathogenic role, if any, in association with HIV has not yet been determined. Studies on *U. urealyticum*, *M. hominis*, *M. salivarium*, and *M. orale* infection rates in HIV-positive and HIV-negative subjects showed no significant differences[151,549]

Mycoplasma and *Ureaplasma* Infections in Immunocompromised Patients

Patients with hypogammaglobulinemia are susceptible to severe persistent infection with *Ureaplasma* spp., *M. hominis*, *M. amphoriforme*, *M. pneumoniae*, *M. salivarium*, and *M. orale*.* Clinical manifestations include osteomyelitis, arthritis, cellulitis, and chronic respiratory tract illness. Patients need to be treated for prolonged periods with high-dose intravenous immunoglobulin and antibiotics to which the specific agents are susceptible. Severe and persistent infections also have occurred in liver, kidney, and bone marrow transplant recipients, as well as other immunocompromised patients.†

Yechouron and associates[1058] reported a 64-year-old man with Hodgkin lymphoma who died of septicemia caused by *Mycoplasma arginini*, an animal pathogen. A similar case was described by Watanabe and Colleges.[1033] Three children with cancer had pneumonia in which bronchoalveolar lavage fluid specimens yielded *U. urealyticum*.[117] Two of the patients died, and the survivor's improvement coincided with erythromycin treatment. A 9-year-old boy had an abdominal infection with *M. hominis* after liver transplantation,[602] and a 15-year-old girl had septic arthritis with *M. hominis* 2 months after renal transplantation.[670]

Mycoplasma and Cancer

Mycoplasma invasion into human cells and subsequent chronic inflammatory processes have been proposed as potential mechanisms of tumorigenesis, alone or in conjunction with other oncogenic infections. Studies have attempted to link *Mycoplasma* infections with prostate cancer and lung cancer.[822] Charles Rosser's laboratory has been able to induce malignant transformation of human prostate cells in vitro using *Mycoplasma*.[719] Studies have also found an increased rate of *M. hominis* infection in patients with prostate cancer.[51] Studies in women with high-grade cervical dysplasia found that a majority were also infected with *Ureaplasma* spp. with or without *M. hominis*.[262] Genital mycoplasmas have been considered an important cofactor for human papillomavirus infection.[78,262]

Mycoplasma as a Cell Culture Contaminant

When *Mycoplasma* spp. were still first being recognized as human pathogens, they were also being studied as a prevalent and serious contaminant in the research and biopharmaceutical industries.[29] Because they are slow-growing, pleomorphic, and resistant to β-lactams and other antibiotics frequently used to eliminate bacteria from cell culture media, contamination is often difficult to identify. Possible sources of *Mycoplasma* include animal- and plant-derived raw materials in culture media and the skin from workers with poor aseptic technique. Fortunately, with better antibiotic options and rapid detection by PCR, these issues are resolving.[631,870]

TREATMENT OF GENITAL MYCOPLASMAS

Having no cell wall, mycoplasmas are naturally resistant to β-lactam antibiotics (i.e., penicillins, cephalosporins, monobactams, and carbapenems), polymyxins, sulfonamides, and vancomycin.[98,1010,1011,1015] Although they may have moderate sensitivity to the aminoglycosides, the minimal inhibitory concentrations (MICs) of these agents for genital mycoplasmas usually are too high for therapeutic use. Tetracyclines and macrolides have been the drugs of choice, although because of concern for tetracycline toxicities and the comparative ease of taking a short course of azithromycin, the latter has come more into favor. Azithromycin is also seen as having the added benefit of treating both gonococcal and chlamydial genital infections when the etiology is not yet identified or could be polymicrobial. However, antibiotic resistance is growing, and some *Mycoplasma* spp. now require alternative regimens. Newer studies show that ofloxacin, moxifloxacin, and levofloxacin have retained good activity against all genital mycoplasmas and ureaplasmas.[60,535,944] When possible, antibiotic susceptibility testing should be performed on all clinically significant isolates. The discovery that genital mycoplasmas may also create biofilms, protecting them from antibiotic activity, would further complicate therapy.[334]

Ureaplasma spp. have retained susceptibility to macrolides, doxycycline, tetracycline, and chloramphenicol. Resistance to ciprofloxacin is developing; however, oxifloxacin and moxifloxacin are still effective and better than levofloxacin.[535] Doxycycline has been recognized as a top choice for ureaplasmal infections while also

*References 32, 308, 323, 688, 797, 823, 906.
†References 184, 450, 481, 609, 677, 785, 914, 1003.

being effective against coinfection with *M. hominis* or gonorrhea.* Erythromycin is also commonly used, although it is less favored as a result of growing resistance[535] and adverse effects. Cardiac toxicity consisting of acute cardiorespiratory deterioration possibly secondary to cardiac arrhythmias has been reported in neonates treated with intravenous erythromycin lactobionate for presumed ureaplasmal pneumonia.[280] Ototoxicity has been seen in adults but not in neonates.[212] Oral erythromycin has been associated with hypertrophic pyloric stenosis in infants younger than 6 weeks.[140] Azithromycin and clarithromycin are active in vitro against *Ureaplasma* spp.,[492,833,905,1013] but their use in neonates has not been evaluated thoroughly. When given orally to infants with very low birthweight colonized with *Ureaplasma* spp., serum levels of clarithromycin at a dose of 7.5 mg/kg every 12 hours were subtherapeutic.[845] For this reason, a dose of 15 mg/kg every 12 hours is recommended. Although the exact duration of therapy is not known, a 10- to 14-day course seems reasonable when clinical improvement and microbiologic eradication are observed during that period.

M. hominis has developed marked resistance to common macrolides, and they are no longer recommended for treatment.[833,1013] By contrast, 16-membered ring macrolides such as josamycin and related lincosamides have shown effectiveness against *M. hominis;* however, they have not been extensively studied and are not FDA approved in the United States.[492,535,782,1069] Other therapies include chloramphenicol, clindamycin, rifampicin, quinolones (i.e., ofloxacin and moxifloxacin), and tetracyclines (doxycycline especially).[60,516,1010] *M. hominis* is usually sensitive to tetracyclines, and these antibiotics should be used if the benefits outweigh the risk for toxicity.[98,121,933,951,1042] During the past decade, resistance of *M. hominis* to tetracycline itself has increased; however, doxycycline remains effective.[215,535,644]

M. genitalium remains sensitive to macrolides and some quinolones such as moxifloxacin.[384,923,944,964] Azithromycin has been a favored choice because it also treats both gonococcal and chlamydial genital infections when the etiology is not yet identified or could be polymicrobial. However, resistance of *M. genitalium* to azithromycin is beginning to appear; therefore, 5-day dosing is being recommended over single-dose treatment.[97,175,462,886] Extended dosing with azithromycin has been found to be significantly more effective than even multidose doxyclycline.[83,665]

Mycoplasmas are not susceptible to the antimicrobial agents routinely used to treat neonatal infections. The decision to cover for possible mycoplasmal infection should be based on the clinical picture and culture results. In general, isolation of mycoplasmas from a normally sterile site in an ill neonate is an indication for consideration of treatment. The possibility of *Mycoplasma* infection also should be suspected when a child appears septic and is not responding to standard antibacterial or antiviral therapy, and appropriate samples for *Mycoplasma* culture or PCR assay should be obtained. However, no large randomized clinical trials have determined the efficacy of treatment in neonates. Experience on which to base treatment decisions, the choice of drug, and the duration of therapy is very limited.[1025]

*References 57, 516, 535, 637, 995, 1010, 1020, 1069.

Isolation of mycoplasmas from endotracheal secretions is not diagnostic of pneumonia, and most of these infants do not require any antimycoplasmal therapy. However, if pneumonia is suspected and the infant's clinical condition is deteriorating, a trial of therapy may be indicated despite the unknown efficacy of treatment. Azithromycin has been used for its anti-inflammatory properties to protect infants from BPD. However, the safety and efficacy of azithromycin in infants with very low birth-weight has not yet been studied.

Mutations in antibiotic targets that confer resistance have been identified, as well as resistance genes carried on plasmids or transposable genetic elements, sometimes conferring resistance to multiple groups of antibiotics.* Recently a group has shown that if the site of the mutation is known, high-resolution melt analysis can be used to rapidly identify antibiotic resistance patterns at the time of the initial diagnosis and eliminate the risk for treatment failure.[984]

PREVENTION OF GENITAL MYCOPLASMAS

Erythromycin administered between 26 and 35 weeks' gestation to pregnant women colonized with *Ureaplasma* spp. was not effective in reducing adverse outcomes such as preterm delivery, low birth-weight, or premature rupture of membranes.[270] In the ORACLE I study,[499] in which the use of broad-spectrum antibiotics was evaluated in mothers with premature rupture of membranes, use of erythromycin was associated with prolongation of pregnancy, reduction in neonatal treatment with surfactant, decrease in oxygen dependence at 28 days of age and older, fewer major cerebral abnormalities on ultrasonography before discharge, and fewer positive blood cultures. The ORACLE II study, which consisted of 6295 women with spontaneous preterm labor, intact membranes, and no evidence of clinical infection, showed that none of the trial antibiotics were associated with a lower rate of the composite primary outcome events than occurred in placebo recipients.[500] Because erythromycin therapy does not eliminate *Ureaplasma* spp. from the lower genital tract, it most likely also does not prevent neonatal ureaplasmal colonization.[752] Smorgick and associates[905] reported on a woman with preterm labor at 27 weeks' gestation and amniotic colonization with *U. urealyticum*, treated with 3 days of ciprofloxacin that was changed to 7 additional days of erythromycin after developing an allergic pruritic reaction. This regimen failed to eradicate the organism, and she was switched to 10 days of intravenous clindamycin and oral levofloxacin. Although there was no further testing of amniotic fluid for infection, the patient was able to delay delivery for 6 weeks and the infant was healthy despite placental pathology revealing chorioamnionitis with acute funisitis. Smorgick and associates[905] support that in cases of *Mycoplasma* spp. intra-amniotic colonization remote from term, expectant management is possible and that fluoroquinolones, clindamycin, or both may be more effective than erythromycin.

*References 460, 461, 535, 782, 885, 886.

The effect on the effect of erythromycin on prevention of neonatal disease has not been evaluated fully.[26] Administration of erythromycin to preterm infants whose mothers had *Ureaplasma* spp. in their lower genital tract reduced respiratory tract colonization but did not decrease the duration of supplemental oxygen therapy[474] or chronic lung disease.[96,608] Treating infants with very low birthweight who have respiratory tract colonization with *Ureaplasma* spp. to prevent chronic lung disease cannot be recommended at present.[118]

Patients with nongonococcal urethritis should be treated with tetracycline 40 mg/kg/day every 6 hours; persons weighing more than 50 kg should receive 500 mg every 6 hours for 10 days.[388,412] *Chlamydia* and *Ureaplasma* are also sensitive to erythromycin, so this antibiotic is a useful alternative for patients in whom tetracycline is contraindicated. With adolescent patients, it is prudent to seek out and treat the sex partners whenever possible.

SECTION **XXI**

FUNGAL DISEASES

CHAPTER 196

Classification of Fungi

David A. Bruckner • Eszter Deak

Fungal infections are an important and growing cause of morbidity and mortality. This is largely due to an expanding population of immunosuppressed individuals who serve as susceptible hosts, including persons with human immunodeficiency virus (HIV) infections, recipients of solid organ or hematopoietic stem cell transplants, and patients with hematologic malignancies, burns, and indwelling medical devices. Less than 50 of the more than 100,000 currently identified species of fungi are known primary pathogens in humans, but many fungal organisms previously thought of as contaminants in clinical specimens are now recognized as etiologic agents of disease under the right circumstances. The challenging task of the clinical microbiologist is to learn to recognize and correctly identify clinically relevant fungi to guide proper patient management.

Medically important fungi belong to the kingdom Fungi.[5] These organisms are classified by their basic growth pattern as yeasts or molds. Yeasts are unicellular fungi that reproduce by budding (*Candida* spp.) or by fission *(Schizosaccharomyces pombe)*. The buds produced by infectious yeasts, termed *blastoconidia*, can form chains, or *pseudohyphae*. Molds are multicellular fungi that grow by means of filamentous cell projections, or *hyphae*. The nuclei in different cells may or may not be separated by characteristic cross walls, or septa. Many medically important fungi change from a multicellular hyphal form in the natural environment or in vitro to a budding single-celled yeast form in tissue. These pathogens are known as *dimorphic* fungi and include *Blastomyces dermatitidis*, *Histoplasma capsulatum*, *Paracoccidioides brasiliensis*, and *Penicillium marneffei*.[6,8]

Fungi may reproduce sexually or asexually. The sexual form of growth is the teleomorph, and the asexual form is the anamorph. Some fungi appear to have more than one name. Often this is because the anamorph and teleomorph were described and named at different times, without the connection between them being recognized. As a result, the teleomorph and the anamorph forms of the same fungus have different names. *Emericella nidulans*, for example, is the teleomorph for the anamorph *Aspergillus nidulans*. Some teleomorphic fungi can produce more than one asexual form of propagation. *Pseudallescheria boydii* is the teleomorph of two anamorphs, *Scedosporium apiospermum* and *Graphium eumorphum*. These three names all refer to the same organism. Although the sexual means of reproduction forms the basis of the taxonomy of fungi, it is the anamorph that is usually obtained in culture. For this reason, the anamorph name is usually used in reports from a clinical microbiology laboratory.

The kingdom Fungi is currently divided into seven phyla.[1,3,6,8] The medically important fungi are contained within the phylum Ascomycota, phylum Basidiomycota, and what was previously named phylum Zygomycota, for which sexual spores and their mode of production form the main basis for classification.[2,4,7] Accepted fungal scientific names are published by the International Code of Nomenclature for Algae, Fungi and Plants (ICN). The phylum names and the type of sexual spore formed by its members are as follows:

1. Zygomycota (zygospores)
2. Ascomycota (ascospores)
3. Basidiomycota (basidiospores)

The phylum Zygomycota is no longer accepted because it is not monophyletic. Organisms previously assigned to the phylum Zygomycota have been divided among subphylum Mucormycotina and subphylum Entomophthoromycotina within the phylum Glomeromycota.[1,3,6,8] Current fungal taxonomy and classification into phyla and subphyla is presently based on both the mode of sexual reproduction and concordant multilocus DNA sequences. Asexual fungi with no known teleomorph phase, previously characterized as a separate formal group known as the "Fungi Imperfecti" also have been designated to the familiar phyla based on molecular phylogenetics.

The taxonomic scheme depicted is based on various sources. The higher level classification of the kingdom Fungi was revised by Hibbett and colleagues.[3]

The basic taxonomic units are the species, and they are grouped into a hierarchical system that includes genera, families, orders, classes, and phyla. The categories may be subdivided (e.g., subphylum, subclass, and suborder) to indicate degrees of relationship. Populations within a given species that have some characteristics in common may be set apart as tribes, varieties, or some other subset designations. Delineation of the zoopathogen *Ajellomyces capsulatus*, the teleomorph of *Histoplasma capsulatum*, is as follows:

Kingdom: Fungi
Phylum: Ascomycota
Class: Ascomycetes
Order: Onygenales
Family: Onygenaceae
Genus: Ajellomyces
Species: *Ajellomyces capsulatus* (anamorph: *Histoplasma capsulatum*)
Variety: The varietal state applies to the anamorph.[5]
H. capsulatum var. capsulatum

H. capsulatum var. duboisii
H. capsulatum var. farciminosum

This chapter includes taxa known to contain medically important fungi. Classes, orders, and families not known to contain pathogens are omitted. More detailed considerations can be obtained by consulting the references.[1-8]

Kingdom: Fungi
- Phylum: Glomeromycota. The teleomorph (sexual form) consists of zygospores. The anamorph (asexual form) consists of sporangiospores within a sporangium.
  - Subphylum: Mucormycotina
    - Order: Mucorales
      - Family: Mucoraceae
        - Genus: *Apophysomyces*
          Lichtheimia
          Mucor
          Rhizomucor
          Rhizopus
      - Family: Cunninghamella
        - Genus: *Cunninghamella*
      - Family: Mortierellaceae
        - Genus: *Mortierella*
      - Family: Saksenaeaceae
        - Genus: *Saksenaea*
      - Family: Syncephalastraceae
        - Genus: *Syncephalastrum*
      - Family: Thamnidiaceae
        - Genus: *Cokeromyces*
  - Subphylum: Entomophthoromycotina
    - Order: Entomophthorales—agents of entomophthoromycoses
      - Family: Basidiobolaceae
        - Genus: *Basidiobolus*
      - Family: Ancylistaceae
        - Genus: *Conidiobolus*
- Phylum: Ascomycota. The teleomorph (sexual phase) consists of ascospores borne in an ascus. The anamorph (asexual phase) may be unicellular yeasts or multicellular molds. This group accounts for 75 percent of all described fungi. Molecular phylogeny studies have been used to define this group, even when a known teleomorph for a given anamorph has not been described.
  - Subphylum: Saccharomycotina
    - Class: Saccharomycetes
      - Order: Saccharomycetales—ascomata absent. Asci are formed singly or in chains. Yeast cells divide by budding or fission.
        - Family: Saccharomycetaceae
          - Genus: *Candida*
            Debaryomyces (teleomorph)
            Kluyveromyces (teleomorph)
            Pichia (teleomorph)
            Clavispora (teleomorph)
            Issatchenkia (teleomorph)
            Saccharomyces (teleomorph)
  - Subphylum: Pezizomycotina—over 90 percent of Ascomycota are mold species
    - Class: Eurotiomycetes
      - Order: Onygenales—ascomata are cleistothecia
        - Family: Arthrodermataceae—agents of tinea (ringworm)
          - Genus: *Arthroderma* (teleomorph)
            Microsporum (anamorph)
            Trichophyton (anamorph)
            Epidermophyton (anamorph)
            Chrysosporium (teleomorph)
        - Family: Onygenaceae—agents of endemic pulmonary mycoses
          - Genus: *Coccidioides* (anamorph)
        - Family: Ajellomycetaceae
          - Genus: *Ajellomyces* (teleomorph)
            Histoplasma (anamorph)
            Blastomyces (anamorph)
            Emmonsia (anamorph)
            Paracoccidioides (anamorph)
      - Order: Chaetothyriales
        - Family: Herpotrichiellaceae—agents of phaeohyphomycoses and chromoblastomycoses
          - Genus: *Capronia* (teleomorph)
            Cladophialophora (anamorph)
            Exophiala (anamorph)
            Fonsecaea (anamorph)
            Phialophora (anamorph)
            Ramichloridium (anamorph)
            Rhinocladiella (anamorph)
      - Order: Eurotiales—ascomata are cleisothecia
        - Family: Trichomaceae—contains the greatest number of human pathogens
          - Genus: *Aspergillus* (anamorph)
            Penicillium (anamorph)
            Talaromyces (teleomorph)
            Emericella (teleomorph)
            Eurotium (teleomorph)
            Neosartorya (teleomorph)
            Paecilomyces (anamorph)
      - Order: Ophiostomales—ascomata are perithecia with long necks
        - Family: Ophiostomaceae
          - Genus: *Ophiostoma* (teleomorph)
            Sporothrix (anamorph)
    - Class: Sordariomycetes
      - Order: Hypocreales—ascomata are mostly perithecia
        - Family: Hypocreaceae—contains agents of mycoses
          - Genus: *Gibberella* (teleomorph)
            Nectria (teleomorph)
            Acremonium (anamorph)
            Fusarium (anamorph)
            Trichoderma (anamorph)
            Verticillium (anamorph)
      - Order: Microascales—ascomata are cleistothecia or perithecia
        - Family: Microascaceae
          - Genus: *Pseudallescheria* (teleomorph)
            Scedosporium (anamorph)
            Microascus (teleomorph)
            Scopulariopsis (anamorph)
      - Order: Sordariales—ascomata are cleistothecia or perithecia; rarely pathogens

Class: Dothideomycetes
Order: Dothideales—ascomata are cleistothecia
Family: Dithoraceae
Genus: *Aureobasidium* (anamorph)
Hortaea (anamorph)
Family: Didymosphaeriaceae
Genus: *Neostudina* (teleomorph)
Family: Mycosphaerellaceae
Genus: *Cladosporium* (anamorph)
Family: Piedraiaceae
Genus: *Piedraia* (teleomorph)
Order: Pleosporales
Family: Pleosporaceae
Genus: *Cochliobolus* (teleomorph)
Bipolaris (anamorph)
Exserohilum (anamorph)
Setosphaeria (teleomorph)
Curvularia (anamorph)
Drechslera (anamorph)
Alternaria (anamorph)
Ulocladium (anamorph)
Lewia (teleomorph)
Class: Pneumocystidomycetes—found as trophozoites, cysts, and intracystic bodies; originally considered members of the kingdom Protozoa
Order: Pneumocystidales
Family: Pneumocystidaceae
Genus: *Pneumocystis*
Phylum: Basidiomycota. The teleomorph is a basidium bearing basidiospores. The anamorphs are yeasts or molds. Arthroconidia are reproductive propagules of some molds.
Class: Tremellomycetes
Order: Tremellales
Family: Filobasidiaceae
Genus: *Filobasidiella* (teleomorph)
Filobasidium (teleomorph)
Cryptococcus (anamorph)
Trichosporon (anamorph)
Class: Ustilaginomycetes
Order: Malasseziales
Family: Malasseziaceae
Genus: *Malassezia* (anamorph)
Class: Agaricomycetes
Order: Agaricales
Family: Schizophyllaceae
Genus: *Schizophyllum*

CHAPTER 197

Aspergillosis

William J. Steinbach

Aspergillosis often has a high mortality, and its incidence is increasing.[10,111,149] Invasive aspergillosis (IA) is now the most common cause of mortality due to the major invasive mycoses, an occurrence that generally is a result of success with prophylactic antifungal regimens and improved diagnostic studies for *Candida* infection. IA is likely also gaining prominence because of the increasing number of severely immunosuppressed patients due to more intensive immunosuppressive therapies for graft-versus-host disease (GVHD) and rheumatologic diseases, increased use of mismatched or unrelated donor transplantations, newer preparative regimens to avoid rejection or relapse, and increase in early posttransplantation survival resulting from better control of bacterial and cytomegaloviral infections.[111,191]

THE ORGANISM

The genus *Aspergillus* contains approximately 185 species, but most human disease is primarily caused by *A. fumigatus*, *A. flavus*, *A. niger*, *A. terreus*, and *A. nidulans*.

The classification of the genus *Aspergillus* has been revised from the original taxonomy to now incorporate both phenotype and morphology as well as newer molecular approaches; consequently, the taxonomy remains dynamic.[154] For instance, newer and pathogenic species have been described, such as *Aspergillus lentulus*,[11] *Neosartorya udagawa*,[188] and *Neosartorya pseudofischeri*,[79] many of which have reduced antifungal susceptibility.[3] *A. fumigatus* causes approximately 90 percent of cases of IA[38] but is difficult to differentiate from the other closely-related species based on morphology. *A. fumigatus* is responsible for most pulmonary disease, whereas isolated sinus disease is caused by *A. niger* and *A. flavus*.[141] Specific determination of the species of *Aspergillus* is clinically important for therapeutic reasons, and a review of *Aspergillus* cultures found that *A. terreus* was seen in only 3 percent of isolates in cases of IA but found exclusively in cases of invasive disease (i.e., no cases of colonization).[141] It has also been well documented that *A. terreus* is resistant to amphotericin B.[167]

Aspergillus is a ubiquitous organism, but its ecologic niche is the soil, where it functions as a saprophytic fungus growing on organic debris and recycling carbon and nitrogen.[202] A classic sexual stage has been identified for *A. fumigatus*,[131] yet the clinical relevance is unclear. Asexual reproduction is abundant and characterized by the production of green pigmented echinulate asexual conidia (spores). The conidia are produced in chains basipetally from the phialides borne on clavate vesicles. This reproductive structure is where the genus name *Aspergillus* is derived, from the aspergillum used to sprinkle holy water in the Roman Catholic mass.

Aspergillus aerosolize conidia, which immunocompetent people asymptomatically breathe every day; it has been estimated that most people inhale several hundred *A. fumigatus* conidia per day.[60] Infection in immunocompromised patients is usually also acquired through inhalation of airborne conidia. Two lines of host defense exist against *Aspergillus*—macrophages and neutrophils—and it appears that both mechanisms of host defense are required for resistance to invasive disease. The first defense is formed by alveolar macrophages, and in vitro murine studies have suggested that resident pulmonary macrophages are responsible for eliminating inhaled *Aspergillus* conidia from the lung.[157,158] If conidia escape, they develop into invasive *Aspergillus* hyphae and become susceptible to neutrophil killing by the release of toxic reactive oxygen species. The host can develop disease through neutropenia, high challenge doses of conidia overcoming macrophages, or corticosteroid suppression of macrophage conidiacidal activity.[46]

A. fumigatus, in particular, is highly successful at causing invasive disease in immunocompromised patients owing to several characteristics, such as thermotolerance, small and abundant pigmented conidia, fast growth rate, production of toxic secondary metabolites, and numerous enzymes involved in breaking down complex polysaccharides. The ability of this fungus to grow at 37°C is crucial for the development of human disease. Although some *Aspergillus* species can grow at this high temperature, it has been reported that *A. fumigatus* can survive at temperatures up to 75°C, and this thermotolerance is likely a major factor in its ability to cause human morbidity.[14] In addition, at 37°C in a nutrient-rich environment *A. fumigatus* can grow at an extremely fast rate.

Conidia are 2.5 to 3.0 μm in diameter, and this small size allows them to remain buoyant in the air for prolonged periods of time and be inhaled deep into the lung alveoli. When inhaled by an immunocompetent person, conidia rarely have deleterious effects because they are cleared by phagocytic cells of the innate immune system. However, severe allergic disease can occur with repeated exposure to large doses of conidia or in those patients who are more atopic. Pigments found on the conidial surface are thought to play important roles in mediating the effects of damaging reactive oxygen species produced by phagocytic cells.[144] Mutants of *A. fumigatus* that lack these conidial pigments are more susceptible to killing by alveolar macrophages than their pigmented counterparts.[97] Whole-genome sequencing of several *Aspergillus* species has revealed that these fungi contain large numbers of enzymes involved in degrading complex polysaccharides.[54] Although these enzymes allow *Aspergillus* species to be enormously successful as saprophytes, it is generally also thought that these enzymes contribute to their ability to cause invasive disease.

Species of *Aspergillus* are also well known for their production of secondary metabolites. Perhaps the most well-known *Aspergillus* metabolite is the carcinogen aflatoxin produced by some strains of *A. flavus*. Although aflatoxin is extremely carcinogenic, its role in the development of human mycoses has not been thoroughly examined. Various suspected putative *Aspergillus* virulence factors have been exhaustively reviewed,[100] and earlier gene disruption studies examined proteases, toxins, hemolysins, melanin pigmentation, and other gene products with little success. It appears the true virulence of *A. fumigatus* is likely a multifactorial combination of attributes.

CLINICAL MANIFESTATIONS

Aspergillus species are relatively unique among pathogens because they are responsible for a gamut of infections extending across the clinical spectrum to include primary allergic reactions, saprophytic involvement, and invasive disease.[114] The type of *Aspergillus* infection generally depends on the immunologic background of the infected host, with immunodeficient patients developing invasive disease while immunoreactive patients have allergic disease. Most frequently encountered among the myriad of clinical presentations are features involving the lungs, such as allergic bronchopulmonary aspergillosis (ABPA) and acute or chronic invasive pulmonary aspergillosis (IPA). Other common infections caused by *Aspergillus* include invasive acute or chronic sinusitis, cutaneous aspergillosis, aspergilloma, and cerebral aspergillosis.[38,114] The clinical manifestations of these infections in immunocompromised patients can be subtle and very nonspecific and commonly occur late in the course of disease. As a result, a high index of suspicion needs to be maintained to implement treatment in the early stages of disease. Unfortunately, the most vulnerable patients against

Aspergillus infections are the least likely to display significant symptoms, adding to the difficulty of diagnosis.[38]

Invasive Pulmonary Aspergillosis

Aspergillus species are ubiquitous in the environment, and one major portal of entry is the respiratory tract. In some immunocompetent patients this inhalation could result in nonpathogenic saprophytic colonization, but in the immunocompromised patient this conidial acquisition will likely result in establishment of invasive disease.[180] IPA is the most frequently documented form of IA and contributes considerably to morbidity and mortality among high-risk patients.[40] In a systematic review of the literature regarding the case-fatality rate of aspergillosis, 70 percent of infections were found to be invasive pulmonary disease.[102] As with other forms of *Aspergillus* infections, the burden of IPA is sustained by immunocompromised patients, including those who have undergone hematopoietic stem cell transplantation (HSCT), solid-organ transplant (SOT) recipients, cancer patients, patients with various congenital immune deficiencies such as chronic granulomatous disease (CGD), and patients treated for autoimmune diseases.[150]

The clinical manifestations of IPA are heterogeneous; typically they may include fever unresponsive to broad-spectrum antibiotics, dry cough, shortness of breath, pleuritic chest pain, hemoptysis, and pulmonary infiltrates on radiography.[4] Although neutropenic patients more commonly have a fever, in about 20 percent of patients the fever and cough will not be present for the first several days of infection,[114] specifically in patients receiving high-dose corticosteroid therapy.[71] In general, disease is often bilateral diffuse pulmonary infection; and dyspnea is a more common presentation in these patients. Progression of infection is characterized by invasion of small vessels, leading to hemoptysis as a leading symptom of IPA in some neutropenic patients. Two patterns of hemorrhage may be identified: (1) hemorrhagic infarction due to vascular invasion and (2) formation of mycotic aneurysms during recovery from neutropenia that can rupture and result in fatal hemoptysis.[122]

Whereas cancer patients undergoing treatment constitute the majority of patients at risk for *Aspergillus* infections, another largely pediatric patient population deserving a separate discussion is those with underlying CGD. IPA is the leading cause of mortality in this patient population. Patients with CGD have an estimated 33 percent lifetime risk for IA, and IPA may, in fact, be the first manifestation of CGD. Although disease in most patient groups is caused by either *A. fumigatus* or *A. flavus*, most cases of *A. nidulans* infection have been reported in patients with CGD.[27] In one review, *A. nidulans* occurred in six patients with CGD but did not occur in any other patient group.[161] Although *A. fumigatus* was more common than *A. nidulans* in CGD patients, infection with *A. nidulans* was significantly more likely to be refractory to antifungal therapy and result in dissemination and death.

In addition to differences in the epidemiology of specific *Aspergillus* isolates, the clinical presentation in patients with CGD can be unique from neutropenic patients. Unlike the acute, rapidly progressive illness described for other immunocompromised patients, in patients with CGD the clinical course is characterized by an insidious onset of fatigue, fever, increased sedimentation rate, and pneumonia.[161] A patient with CGD often does not have typical clinical features (and may possibly be completely asymptomatic) or may have only an elevated erythrocyte sedimentation rate in the setting of no fever. In early disease there is an acute neutrophilic response where the neutrophils surround hyphae. However, in patients with CGD the hyphae remain intact, owing to impaired neutrophil-mediated killing of hyphae. In this setting, IPA in a patient with CGD is a chronic progressive infection that may spread locally to involve pleura, vertebrae, and the chest wall. *Aspergillus* osteomyelitis is a common presentation in patients with CGD, often involving the rib, vertebrae, or femur.[47] Specifically, thoracic wall extension of pulmonary IA has been repeatedly noted.[200] In a study of 24 cases of osteomyelitis caused by *Aspergillus* species in 22 CGD patients, 14 isolates (58%) were due to *A. nidulans* and 10 were due to *A. fumigatus*.[48]

In contrast to patients with neutropenia, hyphal angioinvasion is not a feature of disease in patients with CGD. The "halo" sign (angioinvasion with surrounding tissue ischemia), cavitated lesions, and pulmonary infarcts are not typical in patients with IA and CGD.

Invasive *Aspergillus* Sinusitis

Fungal sinusitis can manifest as allergic, saprophytic, or invasive disease. Invasive *Aspergillus* sinusitis is likely underdiagnosed owing to its variable clinical presentation and difficulty in establishing the diagnosis[38,71,114] possibly because of a decreased inflammatory response in affected patients. Patients can have nasal congestion, discharge, headache, facial pain or swelling, and abnormal findings of the nasal cavity such as pallor of the nasal septum or turbinate mucosa. Epistaxis, orbital swelling, and high fever also can be present.[124] However, the definitive diagnosis can be best established by endoscopic evaluation and selective biopsy. Common findings on endoscopy include pallor of the mucosa and discoloration or granulation of the mucosa due to ischemia as a result of angioinvasion; and, as the disease progresses, a blackened necrotic focus can be found (Figs. 197-1 and 197-2). Extension into bony structures can occur at the site of necrosis leading to spread of disease into adjacent structures, such as the orbit and the brain, which carries a high mortality rate.

Although imaging is not diagnostic, it can aid in establishing the diagnosis because it can be used as a roadmap for endoscopy by showing which sinuses are involved (Fig. 197-3). In a review of 25 patients with rhinosinusitis, 44 percent showed evidence of invasion beyond the sinus cavities on computed tomography (CT).[58] In the same study, however, 12 percent of patients had negative CT findings, again highlighting that a high index of clinical suspicion must guide establishment of the diagnosis to ensure the best outcome.

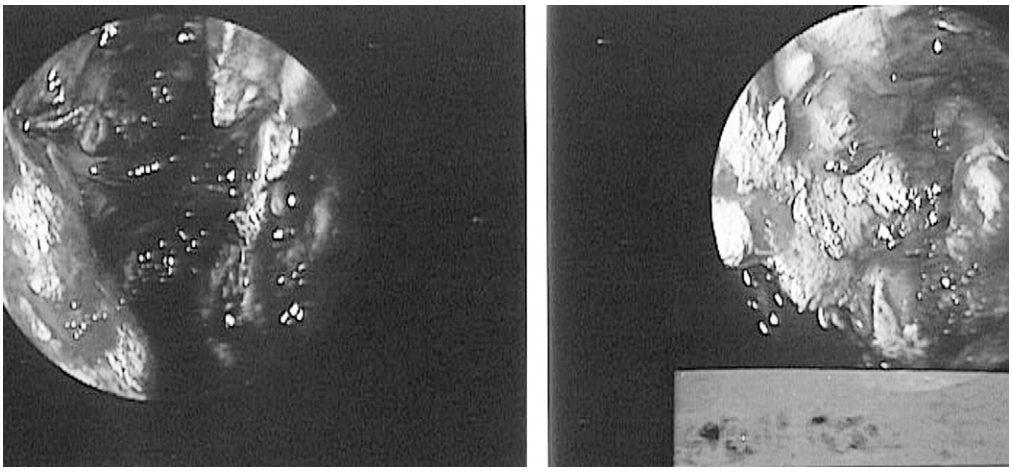

FIGURE 197-2 ■ Same patient as in Figure 197-1. Endoscopy shows necrotic mucosa at the basilar skull area.

Cerebral Aspergillosis

Aspergillus infections most commonly involve the lungs, but disease can disseminate via the bloodstream and involve distant organs. One of the most frequent sites of dissemination is the central nervous system (CNS).[63] Cerebral aspergillosis may also be a result of direct extension through the sinuses. There are studies that have estimated that CNS aspergillosis may be found in 40 to 50 percent of patients with IA and acute leukemia or allogeneic stem cell transplant.[77,156] As with other *Aspergillus* infections, *A. fumigatus* is the most frequently encountered species in cerebral aspergillosis, but other implicated species are *A. flavus*, *A. niger*, and *A. nidulans*.[78] Clinical presentation often does not include more classic symptoms for an intracranial process, such as headache, nausea, or vomiting. Instead, patients have an altered mental status, convulsions, hemiplegia or hemiparesis, ophthalmoplegia, and loss of consciousness. Severely immunocompromised patients may not display these symptoms, and their disease progresses more rapidly.

Aspergillus hyphae are angioinvasive and thrombose arteries to create hemorrhagic infarcts and, as a result, CNS aspergillosis can present as solitary or multiple abscesses and, less commonly, as mycotic aneurysms and carotid artery invasion. Cerebral aspergillosis can also appear as meningitis or granuloma.[78] Cerebral aspergillosis presents as multiple areas of low density and no enhancement even with contrast on CT, and lesions are usually located within the basal ganglia and gray-white matter junction. On magnetic resonance imaging (MRI), these same abnormalities appear as foci of intermediate T2-weighted signal surrounded by a rim of higher signal.[133,179] Aspergillosis of the CNS carries a case-fatality rate of nearly 90 percent,[102] so prompt diagnosis and treatment is key to survival. Unfortunately, definitive diagnosis requires biopsy, and typically these patients are often too coagulopathic to undergo such a procedure.

Cutaneous Aspergillosis

Neonates, burn victims, HSCT recipients, SOT recipients, and other immunocompromised patients are the

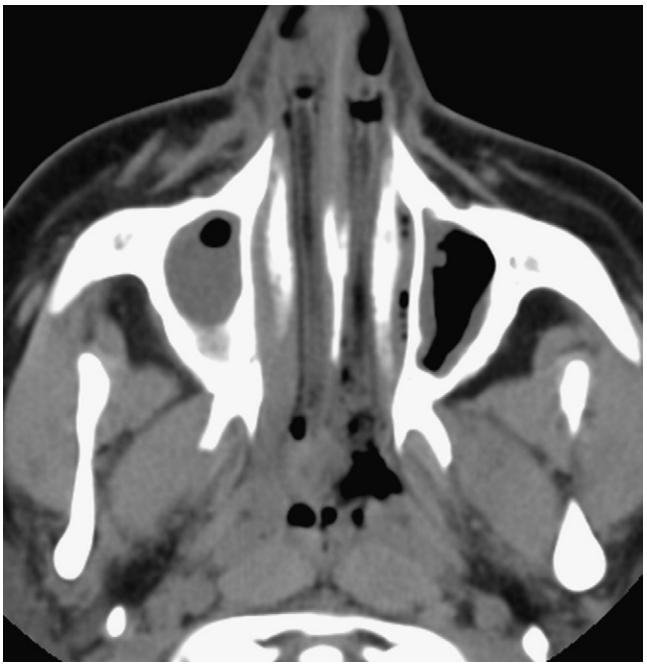

FIGURE 197-3 ■ Same patient as in Figures 197-1 and 197-2. CT shows complete opacification of the right maxillary sinus.

ones most frequently found to develop cutaneous aspergillosis. Although not the most commonly encountered *Aspergillus* infection, cutaneous infection has a reported incidence between 4 and 11 percent.[36,199] Cutaneous aspergillosis can be primary, a result of direct skin injury or traumatic inoculation, or secondary, a result of hematogenous spread or extension from infected underlying structures.[183] Primary cutaneous aspergillosis has been associated with intravenous access devices, adhesive dressings, and sites of burns or surgery. Premature infants are at particular risk because their skin is immature and most vulnerable. HSCT recipients generally develop disease as a result of hematogenous seeding from a primary source, usually the lungs. Lesions often begin as erythematous, indurated papules that progress to ulcerative, painful and necrotic lesions.[170] Treatment involves débridement and excision of necrotic tissue, which provides diagnostic material, and systemic intravenous antifungal agents as well as topical preparations. The role of topical antifungal therapy alone is unclear, because often cutaneous aspergillosis is a harbinger for underlying undiagnosed systemic disease, so relying on topical antifungal coverage alone is likely inadequate.

Chronic Aspergillosis

Chronic aspergillosis is less frequently encountered than acute disease, and the patient population affected is typically distinct as well. A degree of immune suppression does exist in these patients, and exposure to corticosteroids is common. Underlying conditions include corticosteroid use for chronic lung disease, diabetes mellitus, and alcoholism.[38] Patients often have underlying pulmonary disease, such as cavitary tuberculosis, sarcoidosis, emphysema, or fibrotic lung disease. There are three separate categories used to describe chronic aspergillosis.[42] The first is chronic cavitary pulmonary aspergillosis (CCPA), in which multiple cavities form and expand and may be occupied by fungus balls. The second is chronic fibrosing pulmonary aspergillosis, which, as the name connotes, is characterized by progression of the cavities into extensive pulmonary fibrosis. The final category has been defined as chronic necrotizing pulmonary aspergillosis (CNPA), also known as either subacute invasive or semi-invasive pulmonary aspergillosis.[42] The latter category is an indolent pulmonary infection of patients with a mild or moderate defect in immune function, such as in the setting of prolonged corticosteroid use, and may be seen after resolution of neutropenia.[114] CNPA is a slowly progressive disease, and clinical signs observed include, cough, fever, fatigue, and weight loss.

The most serious complication from chronic pulmonary aspergillosis is potentially life-threatening hemoptysis. Diagnosis of chronic disease requires biopsy, and treatment is with long-term antifungal therapy.[85] Management of CCPA can sometimes be via surgical resection, although long-term antifungal therapy, as for IA, is indicated. Management of CNPA is similar to that of IPA, although the disease is more indolent; thus, there is a greater emphasis on long-term oral therapy.

Aspergilloma

Aspergillomas consist of a mass of tangled hyphae, cellular debris, fibrin, and few inflammatory cells. They develop as a complication of existing cavitary lesions and are typically found in the upper lobes where there is poor drainage.[114,180] The cavitary lesions may result from tuberculosis, sarcoidosis, bullous emphysema, and other diseases. *A. fumigatus* typically causes pulmonary aspergilloma; and although patients may remain asymptomatic, many have recurrent hemoptysis. Perhaps the earliest radiographic sign is pleural thickening of a preexisting lung cavity. Later, as the fungus ball develops, CT or plain radiography will show a solid and round mass within the cavity separated from the thickened wall by an air crescent sign.[62] Aspergillomas can be divided into simple or complex, based on radiologic criteria, with simple aspergillomas lacking constitutional symptoms, paracystic lung opacities, cyst expansion, or progressive pleural thickening.[86] Treatment of active disease is aimed at controlling and preventing complicating symptoms such as hemoptysis, and surgical resection is the definitive treatment. However, given the high morbidity and mortality rate in patients with complex aspergilloma, surgical intervention is reserved for high-risk patients. Other treatment modalities, such as endobronchial and intracavitary instillation of antifungal agents, have been attempted with some success, given that systemic therapy is ineffective at diffusing antifungal agents into the cavity containing the fungus ball.[86,114]

Allergic Bronchopulmonary Aspergillosis

ABPA occurs in asthmatic and cystic fibrosis patients and is a pulmonary disease caused by type I and III

hypersensitivity reactions to *A. fumigatus* allergens. Exposure and inhalation of *Aspergillus* conidia results in saprophytic (noninvasive) colonization of the bronchial airways, which then triggers an IgE-mediated allergic inflammatory response. Over time, bronchial obstruction takes place and patients can have a productive cough, wheezing, and chest pain; fever and malaise are also presenting symptoms.[171]

Diagnosis of ABPA is based on eight primary criteria: (1) history of bronchial obstruction (e.g., asthma), (2) peripheral blood eosinophilia, (3) elevated serum IgE levels, (4) specific IgE and IgG to *Aspergillus* antigen in serum, (5) immediate (type I) skin reactivity to *Aspergillus* antigen, (6) precipitating antibodies to *Aspergillus*, (7) pulmonary infiltrates, and (8) central bronchiectasis. Radiologically, ABPA is characterized by bronchial wall thickening, pulmonary infiltrates, and central bronchiectasis, a result of the type III hypersensitivity reaction.[114,180] The diagnosis of ABPA in patients with cystic fibrosis is difficult because many of the diagnostic criteria overlap with common manifestations of cystic fibrosis.

Treatment depends on relieving inflammation via an extended course of systemic corticosteroids. Addition of the antifungal agent itraconazole is used to decrease the fungal burden and diminish the inciting stimulus for inflammation.[24,29,172] Because disease activity is correlated with serum IgE levels, monitoring of IgE levels can be used as a marker to define duration of therapy.

EPIDEMIOLOGY

It is critical to understand both the risk factors of the individual patient and the epidemiology of the pathogen to predict both likelihood of disease development as well as outcome. Host factors are paramount, and the clinician needs to take into consideration the underlying and concomitant diseases as well as the degree and type of immunosuppression. IA was the most common mold infection in a review of approximately 5500 patients who underwent HSCT; although more than 7 percent of HSCT recipients had mold infections, *Aspergillus* infections were the most common, followed by *Fusarium*, Zygomycetes, and *Scedosporium* infections.[111] IA is the leading cause of infectious death in HSCT recipients, and one study showed that 36 percent of all confirmed nosocomial pneumonia in these patients was caused by *Aspergillus* infection, with a crude mortality of 95 percent.[135] The incidence of *Aspergillus* infection in HSCT recipients has ranged from 3 to 7 percent,[118,203] but the true incidence is likely dependent on multiple factors. In one study of HSCT patients with IA, the risk for developing the disease was 12.8 times higher among recipients of allogeneic than autologous HSCT.[129] A retrospective review of 409 patients showed 13.1 percent had IA, which represented 17.2 percent of all isolated pathogens in allogeneic transplant recipients and 3.8 percent in autologous transplant recipients.[92]

A large prospective French study analyzed 424 cases of IA and found an incidence of 0.9 percent in autologous and 8.1 percent in allogeneic HSCT patients, respectively,[103] highlighting a consistent finding that IA occurs much more readily in the allogeneic HSCT recipient. Among SOT recipients, the highest incidence of IA was for heart transplant recipients (4.8%), followed by lung transplant recipients (4.1%), and significantly dropping for liver (0.8%) and kidney (0.3%) transplant recipients, findings that have also continued through most larger studies. The majority of patients with IA had a hematologic malignancy, and the largest group had acute leukemia (35%), but the second largest group had chronic lymphoproliferative disorders (22%). For those with acute leukemia, IA occurred in 68 percent during the induction phase of chemotherapy, when cytotoxic agents are generally the most intense, and in 27 percent during the consolidation phase. The time to developing IA after transplantation was similar in different transplantation settings, with 68 percent diagnosed more than 100 days after HSCT and the majority (18/27) of SOT recipients with IA diagnosed at least 100 days after transplant. Multivariate analysis showed factors independently associated with increased risk for death included older age, diagnosis based on positive culture with two positive galactomannan assays, and presence of pleural effusion or CNS involvement. Mortality in patients with acute leukemia was 38 percent, whereas allogeneic HSCT recipients had a staggering 56 percent overall mortality.

The Transplant Associated Infection Surveillance Network (TRANSNET) study sponsored by the Centers for Disease Control and Prevention evaluated HSCT and SOT recipients from 23 U.S. medical centers (2001-2005) and included evaluation of a total of 642 cases of IA.[9] Twelve-month cumulative incidence of IA in all HSCT recipients was 1.6 percent, compared with 0.63 percent in SOT recipients. Twelve-week all-cause mortality was 57.5 percent among HSCT recipients and 34.4 percent among SOT recipients. Multivariable analysis demonstrated that neutropenia, renal insufficiency, hepatic insufficiency, early onset (<30 days) IA, proven IA, and methylprednisolone use, often for GHVD, were independently associated with mortality. Analysis for SOT recipients revealed that hepatic insufficiency, malnutrition, and CNS disease were independently associated with increased risk for death. Among both HSCT and SOT recipients, receipt of voriconazole as part of the initial antifungal therapy was more common among survivors.

A TRANSNET focus on just the 875 HSCT recipients found IA was the most common (43% of all invasive fungal infections), followed by invasive candidiasis (28%).[91] The median age at development of IA after HSCT was 99 days. Of the 80 cases of IA in autologous HSCT, 50 percent occurred within 1 month after receipt of the transplant, whereas in allogeneic HSCT recipients only 22 percent occurred within 1 month after transplantation. Autologous HSCT recipients had all-cause mortality of 13 percent at 12 months, whereas in allogeneic recipients it was 36 percent at 12 months. The 12-month cumulative incidence for IA in all HSCT recipients was 1.6 percent, compared with 1.1 percent for invasive candidiasis, and the overall 1-year survival among HSCT recipients with IA was only 25.4 percent.

Another large database, the Prospective Antifungal Therapy (PATH) Alliance, also found IA most frequent

among HSCT recipients, and approximately 70 percent of those HSCT recipients with IA were allogeneic transplants. The median time to develop IA after HSCT was similar (82 days), with a diagnosis of a median of 51 days after autologous transplant and 83 days after allogeneic transplants.[126] Another study in HSCT recipients found prognostic factors at diagnosis strongly related to death due to IA were dissemination of IA, pleural effusion, low monocyte count, and corticosteroids within the previous 2 months as well as the receipt of a dose 2 mg/kg or more at the time of diagnosis and uncontrolled GVHD.[31]

There is a well-characterized bimodal distribution of aspergillosis in HSCT recipients that correlates with preengraftment neutropenia (median of 16 days after transplantation) and the peak of GVHD (median of 96 days after transplantation).[190] This likely relates to the two major mechanisms of protection against IA: alveolar macrophages and granulocytes. Most patients (86%) with autologous transplants were diagnosed with IA while neutropenic, whereas patients with allogeneic transplants were at greatest risk after engraftment or during impairment of cell-mediated immunity due to cytomegaloviral infection or GVHD.[190] In large reviews of patients undergoing allogeneic HSCT, IA was diagnosed at a mean of 88 to 115 days post transplant,[115,129,149,156] with mortality exceeding 80 percent. In some studies, most cases were diagnosed after day 30,[115,129] and in one study no cases of IA were diagnosed during the neutropenic period after transplantation.[76]

The TRANSNET database also analyzed all invasive fungal infections among SOT recipients and found IA (19%) was the second most common invasive fungal infection, and, unlike HSCT recipients, invasive candidiasis (53%) was more common in SOT recipients.[136] The median time to onset of IA was 184 days after SOT transplantation, with a 1-year incidence of developing IA at 0.65 percent and a 12-month survival of 59 percent. The PATH Alliance analysis in SOT again found IA (25%) second to invasive candidiasis, but IA was more common in lung transplant recipients (60%).[125] IA developed a median of 400 days after transplantation, which was a median 100 days after liver transplantation, compared with 504 days and 384 days in lung and heart transplant recipients, respectively. Most cases of IA in liver transplant recipients occurred less than 6 months post transplant, whereas 62 percent of lung transplant recipients with IA developed disease after 1 year. This contrasted to a retrospective review of 158 cases of IA in Spanish SOT recipients in which it was found that 57 percent had early-onset IA (first 3 months after transplantation) yet the mean time to develop IA was still 234 days.[55] The overall incidence of IA in their SOT recipients was 1.4 percent, including a similar distribution among specific organ transplants, with an incidence of 3 percent (lung), 2.4 percent (heart), 2 percent (liver), and 0.2 percent (kidney). Overall mortality was 77 percent with no significant differences between SOT groups. Risk factors for developing early-onset IA included a complicated postoperative period, repeated bacterial infections or cytomegaloviral infection, and renal failure.

Factors associated with attributable mortality for patients with IA include allogeneic HSCT or SOT versus hematologic malignancy, disease progression, corticosteroid use (≥0.2 mg/kg), renal insufficiency, neutropenia (<500 cells/μL), disseminated IA, diffuse pulmonary involvement, and possible IA.[130] One study found the all-cause mortality (47.8%) was similar to attributable mortality from IA (40.2%). This study again found receipt of voriconazole as initial antifungal therapy led to greater overall survival (69.4% vs. 49.0%) compared with use of amphotericin B or itraconazole as initial therapy. A different study found that 74 percent of the deaths in patients with IA occurred in the first 6 weeks after initiating therapy, and the majority (68%) of those deaths were attributable to IA, whereas most deaths after 6 weeks of therapy were judged to be due to underlying disease and its treatment and not attributable to IA.[204] Again, there was a difference between amphotericin B and voriconazole as initial therapy related to deaths due to IA, but no difference between voriconazole and amphotericin B in deaths due to all causes other than due to IA.

A unique study found that the majority (59%) of patients with IA had neutropenia as a risk factor, most of whom had hematologic or solid malignancies. Among the 41 percent of non-neutropenic patients, most had corticosteroid-treated chronic obstructive pulmonary disease, asthma, or rheumatologic disorders. Compared with neutropenic patients, the non-neutropenic patients were significantly less likely to have symptoms of IA and more likely to have frequent intercurrent pneumonia with another microorganism. The mortality rate was significantly higher among non-neutropenic (89%) compared with neutropenic patients (60%) with IA,[35] yet the sensitivity of galactomannan antigenemia was similar (approximately 65%) for neutropenic and non-neutropenic patients.

The risk for IA is calculated to increase from 1 percent per day after the first 3 weeks of neutropenia to 4 to 5 percent per day after 5 weeks,[160] with a 70 percent incidence after neutropenia exceeds 34 days.[57] Prolonged or marked macrophage dysfunctions that occur as a result of underlying disease and its treatment can also predispose patients to IA. Therefore, risk for infection is higher with advanced underlying disease, transplantation during relapse of malignancy or chemotherapeutic rescue therapy, GVHD, or concurrent infection such as from cytomegalovirus.[160] In a survey of 24 medical centers of 148 patients with IA, 30 percent also had a bacterial infection, 20 percent also had a viral infection, and 19 percent also had another fungal infection.[141]

Corticosteroids are also a well-known major risk factor for the development of IA and can suppress the ability of monocytes/macrophages to kill conidia through inhibition of nonoxidative processes and impairment of lysosomal activity. Corticosteroids also inhibit polymorphonuclear neutrophils in their chemotaxis, oxidative bursts, and activity against hyphae.[49] Generally, corticosteroids suppress macrophages whereas cytotoxic chemotherapy decreases neutrophil number and function. Corticosteroids also greatly accelerate the growth of *A. fumigatus*; in one study the doubling time increased to 48 minutes.[127]

In several HSCT patient risk factor studies, only moderate-to-severe GVHD and corticosteroid prophylaxis

for GVHD[12,115,149,206] and total-body irradiation[206] were significant variables in the multivariate analyses. In one study, several parameters were found to influence survival in the period from HSCT to diagnosis of fungal infection, all related to cumulative dose of prednisolone. In the multivariate analysis, relative risk (RR) was 8.78 of death from IA in patients with acute active GVHD (grade 2 or more) or extensive chronic GVHD combined with a cumulative total prednisolone dose of greater than 7 mg/kg dose 1 week before diagnosis.[149]

There is little specific information on the fundamental epidemiology of pediatric IA, and most epidemiologic investigations do not offer pediatric analyses.[34,53,92,206] One study found that the highest incidence of IA was seen in children who had undergone allogeneic bone marrow transplantation (4.5%) and those with acute myelogenous leukemia (4%). Specifically, the incidence of IA in patients with acute myelogenous leukemia was significantly greater than the incidence in patients with acute lymphoblastic leukemia (RR, 5.6; 95% confidence interval [CI], 4.6 to 7.0).[207]

The largest analysis was a retrospective multicenter study of 139 children with IA. *A. fumigatus* was the species most frequently recovered (52.8%), and the majority of the children had a malignancy with or without HSCT. Significant risk factors that impacted survival were immunosuppressive therapies and allogeneic stem cell transplant. Analysis did not show superiority of any one antifungal agent related to overall mortality, and 52.5 percent (73 of 139) of the children died during treatment of IA.[22]

Analysis of a large pediatric inpatient database found an annual incidence of 0.4 percent of IA among immunocompromised children, and the majority of cases included an underlying malignancy.[207] The highest incidence for IA was 4.5 percent among children who underwent allogeneic HSCT and 4 percent among patients with acute myelogenous leukemia, whereas autologous HSCT had a lower incidence of 0.3 percent. Lung SOT recipients had the greatest incidence among those pediatric SOT recipients (5%). Children with CGD had an incidence of 6.5 percent, whereas those with Wiskott-Aldrich syndrome (n = 267) had an incidence of a staggering 30 percent. Comparing mortality in pediatric patients with specific underlying diseases with and without IA revealed the relative risk for death was increased in CNS tumors (RR, 21.6), acute lymphocytic leukemia (RR, 14.9), and lymphoma (RR, 13.5), showcasing the overall good survival rates of those common pediatric malignancies and the devastating effect of adding IA to reasonably curable underlying pediatric malignancies.

Pediatric patients undergoing transplantation are generally less vulnerable to all infections than their adult counterparts,[51] and a review of 585 infections in 276 children who underwent HSCT found 38 (6%) with mold infections in the first year after transplantation, including 28 *Aspergillus* infections.[12] A larger report reviewed 510 pediatric HSCTs in 485 patients from 1990 through 1998.[12] There were 26 IA cases (4.79% of infections) in 584 culture-proven infections during the first year post transplant. This pediatric report was the first to employ tools beyond descriptive statistics to analyze pediatric IA. A multivariable analysis showed that IA was more likely to be associated with severe GVHD (RR, 7.5%; 95% CI, 3.0 to 18.4). Additional analyses revealed that in the first 30 days there were 10 cases of IA, 13 cases from day 31 to 100 post transplant, and 3 cases from day 101 to 365 post transplant.

In an excellent review of IA case-fatality rates pooled from 1941 patients from clinical trials, cohort or case-control studies, and case series of 10 or more patients with definite or probable IA from 1995 through 1999, there was some stratification of case-fatality rate by decade of life.[102] The mean age of all patients was 44.2 years (range, 3 to 91 years), and the youngest cohort (≤20 years) had a case-fatality rate of 68.2 percent (15/22). The next highest case-fatality rate was 59.3 percent in the age group from 21 to 30 years. This suggests the epidemiologic possibility that pediatric and adult IA differ in outcome.

DIAGNOSIS

The diagnosis of IA is often not straightforward. Because of the many clinical presentations, an IA diagnosis is categorized as "proven," "probable," or "possible" disease based on meeting certain clinical, microbiologic, and radiologic criteria designed and later revised by the European Organization for the Research and Treatment of Cancer and the Mycoses Study Group (EORTC/MSG).[7,37] These criteria have served as a standard in clinical trials to group patients with similar disease characteristics, but it should be noted that these criteria are not perfect and the designers have specifically cautioned against their implementation in routine clinical practice. Nonetheless, these distinctions have served the community well to establish a common framework for discussion about disease in the complicated high-risk patient. Generally, "proven" and "probable" IA can be considered as one entity because numerous clinical trials have shown their general equivalency in patient outcomes. However, "possible" disease is a vague entity and should be excluded from clinical trial design and the clinical diagnosis strongly reconsidered.

Cultures

A proven diagnosis of IA requires isolation from an otherwise sterile culture and histologic demonstration (Fig. 197-4).[37] However, this "gold standard" of tissue biopsy is often considered too invasive and complicated by bleeding or secondary infection in high-risk patients. An important distinction for a positive *Aspergillus* culture has to be made between disease and colonization. A 1-year retrospective study found that only 12 percent of patients with *Aspergillus*-positive cultures met criteria for IA. Among high-risk patients, a positive culture was associated with IA in 50 to 65 percent of cases; among intermediate-risk patients, this occurred in 8 to 28 percent, whereas patients with low risk rarely had IA.[141]

In one study the predictive value of respiratory tract cultures from patients with IPA was 40 to 100 percent.[181] Even in patients with established disease the sputum

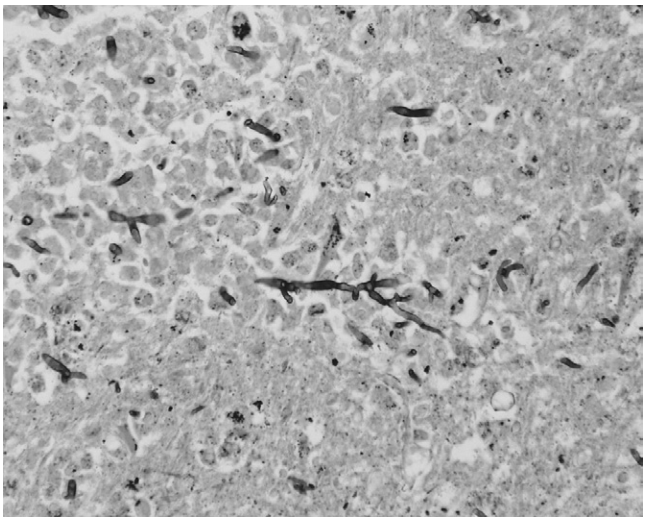

FIGURE 197-4 ■ Histopathologic findings after a lung biopsy of invasive aspergillosis show septate hyphae (Gomori methenamine silver stain). (Courtesy Dr. Thomas J. Cummings, Duke University Medical Center.)

specimens are commonly negative,[71,152] which is likely because IPA is predominantly infiltrative and does not have aerial growth in the bronchial tree.[71] Colonization with *Aspergillus* species has been a marker for reduced short-term survival, because 12 percent of colonized patients died within 3 months. IPA was diagnosed in 12 percent of patients with a positive culture, but this is likely an underestimate because culture specimens were not always obtained because diagnosis was often made by radiographic imaging.[141] In one study of heart transplant recipients, during a 10-year study period *Aspergillus* species were recovered from 30 episodes from 27 heart transplant recipients (incidence, 10.5%). The overall positive predictive value was 60 to 70 percent, but this increased to 88 to 100 percent when the organism was recovered from a respiratory specimen other than sputum and decreased to 50 to 67 percent when it was recovered from sputum. The sensitivities of fungal and conventional media for the recovery of *Aspergillus* species were 95 to 100 percent and 33 to 38 percent, respectively.[123]

Prior nasal colonization before transplant has been associated as a predictor of subsequent IPA in some studies[2] but has not been duplicated in others.[80] Prior IA does not eliminate the chance of a successful HSCT because in one study there were recurrences in nine patients with IA before transplantation, and all patients showed no signs of delayed engraftment compared with transplant recipients without a history of IA.[162]

Aspergillosis diagnosed by blood culture is rare.[59] In a study of 1477 separate positive cultures, there were more than a dozen positive blood cultures, but most were associated with pseudofungemia or terminal events noted at autopsy.[141] In general, the *Aspergillus* hyphal mass that develops in the lumen during angioinvasion remains in place until the force of blood flow causes hyphal breakage, which then allows the mass to circulate. The likelihood of a blood culture capturing these irregularly and infrequently discharged units is small. The difficulty in detecting *A. fumigatus* in blood culture stands in contrast to other angioinvasive filamentous fungi (e.g., *Fusarium* spp., *Paecilomyces lilacinus*, *Scedosporium prolificans*, *Acremonium* spp.) that have the ability to discharge a steady series of unicellular spores into the bloodstream that are more likely to be captured in a blood sample. This ability to sporulate in tissue and blood has been termed *adventitious sporulation*.[159] Because *A. terreus* also displays adventitious sporulation, histopathology and examination with potassium hydroxide of these spores also can allow rapid, presumptive identification of *A. terreus*. Therefore, a positive blood culture with *A. terreus* or another mold that demonstrates adventitious sporulation should not be ignored whereas a positive blood culture with other *Aspergillus* species should be further evaluated.

Radiology

IPA characteristically manifests on radiographs as multiple, ill-defined, 1- to 3-cm peripheral nodules that gradually coalesce into larger masses or areas of subsegmental and segmental consolidation. Lobar or diffuse pulmonary consolidation is a common finding.[28] Chest radiographs can be abnormal, but in one series they were normal in approximately 30 percent of patients in the week preceding death.[148]

There are two classic radiologic signs of IPA. The "halo" sign occurs in neutropenic patients with a hemorrhagic nodule due to angioinvasion. An early CT finding of the halo sign is a rim of ground-glass opacity surrounding the nodule. In one study, the halo sign was seen in all patients with biopsy-proven IPA, but it is so nonspecific it was also seen in patients with zygomycosis, organizing pneumonia, or pulmonary hemorrhage.[205] These early lesions subsequently change into a cavitary lesion or lesion with an "air crescent" sign 2 to 3 weeks later when neutropenia recovers.[28,93] In one study this was seen in 48 percent of patients 3 to 10 days after recovery of neutropenia.[156] Cavitation of the nodules or masses occurs in about 40 percent of patients and is characterized by an intracavitary mass composed of sloughed lung and a surrounding rim of air. A retrospective review of the CT finding for 47 autopsy-proven cases of IPA showed that nodular lesions and cavitation occurred significantly more often compared with controls.[65]

Just as the clinical presentation is nonspecific and heterogeneous, so are the findings in radiologic studies (Figs. 197-5 and 197-6). Whereas in most patients disease is seen as round infiltrates, peripheral wedge-shaped lesions, and the typical halo sign early in the course of IPA during the neutropenic period, in patients with CGD the hyphal angioinvasion is not a feature of disease and therefore the halo sign, cavitated lesions, and pulmonary infarcts are not typically found (Fig. 197-7). Instead, there are areas of tissue destruction secondary to a reactive acute and granulomatous inflammatory process.[120]

A long-term CT follow-up in 40 non–human immunodeficiency virus (HIV)-immunocompromised patients with IPA showed that formation of cavitation most strongly predicted time until radiologic remission and beneficial outcome. In that study, the natural history of early IPA lesions was evaluated and it was found that 90

percent of patients experienced an increase in lesion size and number followed by a plateau in size and a decrease in number. Cavitation of the lesions developed in 55 percent of patients, and complete radiologic remission within a median 80 days was observed in 42.5 percent of patients. The number of days until remission without cavitation (50 days) was less than for those with cavitation (95 days), so formation of no cavitation was strongly predictive of radiologic remission.[18] In one study the appearance of the air crescent sign had no relationship to duration of neutropenia and showed a tendency to appear in large lesions such as consolidation or mass rather than small lesions like nodules.[88]

There may be radiologic differences for IA in adult and pediatric patients. In adult series of pulmonary aspergillosis, approximately 50 percent of cases show cavitation and 40 percent show air crescent formation.[56] In one 10-year review of pediatric patients (mean age, 5 years), there was central cavitation of small nodules in only 25 percent of children and no evidence of air crescent formation within any area of consolidation.[179] In another pediatric report there was a 22 percent (6/27) rate of cavitation on chest radiography[5] and in another there was a 43 percent (6/14) rate of cavitation on CT.[177] In these last two pediatric series the mean ages were higher than the other report of lower rates of cavitation and no air crescent formation, suggesting that there is a spectrum of radiologic disease presentation that is directly related to age, with cavitation and air crescent formation more likely in the older child and adult than in the younger child.

A review of 27 pediatric patients showed that radiographic changes that developed after HSCT but before diagnosis of pulmonary fungal infection included unilateral infiltrates (52%) slightly more often than bilateral infiltrates. At the onset the infiltrates were interstitial (41%), alveolar (41%), and mixed (18%). Hilar or mediastinal lymphadenopathy and pleural effusion/thickening were rare. By the time of diagnosis of pulmonary fungal infection the infiltrates were largely bilateral (66%) and alveolar or nodular (74%), including 22 percent of patients who had cavitary lesions.[5] The largest series of contemporary pediatric IA cases found the most common clinical site of IA was the lungs (59%), and the most frequent diagnostic radiologic finding was nodules (34.6%). Importantly, only 2.2 percent of the children showed the air crescent sign, 11 percent demonstrated the halo sign, and cavitation was seen in 24.5 percent of patients.[22]

Thoracic MRI findings are not as characteristic as chest CT findings, and the typical MRI sign is the "target" sign, a nodular lesion with a lower signal in the center compared with a higher, contrast-enhancing signal intensity in the rim on T1-weighted images. This sign is highly suggestive of late-stage disease.[15] MRI is the modality of choice for diagnosing cerebral aspergillosis and is preferred over CT for sensitivity (Fig. 197-8). Findings often show multiple lesions located in the basal ganglia that include an intermediate signal intensity, lack of contrast enhancement, and absence of mass effect.[119] CT of the head often reveals one or multiple hypodense, well-demarcated lesions. Hemorrhage and mass effect are

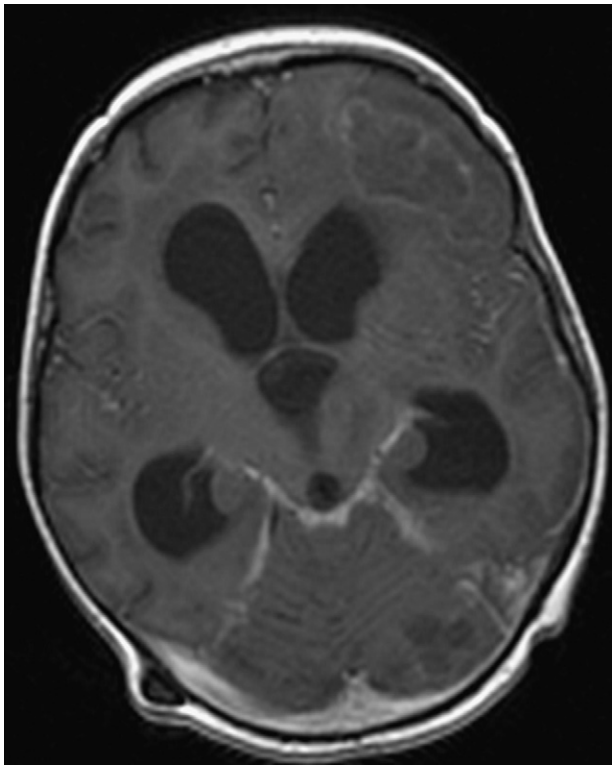

FIGURE 197-8 ■ A 3-year old with medulloblastoma after chemotherapy and irradiation had an acute change in mental status. T1-weighted axial MR image shows multiple lesions in the subcortical area.

unusual, but for patients with adequate peripheral white blood cell counts a ring enhancement and surrounding edema are more frequent.[38] T2-weighted MR images show very decreased signal intensity compared with those of bacterial sinusitis, which show increased signal intensity.[38]

Serology

Serologic testing for antibodies to *Aspergillus* antigens is helpful to diagnosis aspergilloma or ABPA in immunocompetent individuals, but unfortunately serology plays little role in the immunocompromised patient because *Aspergillus* growth does not correlate with an increase in anti-*Aspergillus* antibody titers.[100] For example, serologic examination of 18 patients with IA showed anti-*Aspergillus* antibody detection was negative in all cases, likely owing to profound immunosuppression.[156]

However, despite the historical lack of success with antibody testing, there is a movement to utilize antibody testing in patients before immunosuppression in an attempt to discern who is most likely to subsequently develop IA. In a study to evaluate antibody responses using an enzyme-linked immunosorbent assay (ELISA) format in different types of aspergillosis, patients showed that three recombinant antigens may have an important diagnostic potential.[155] The recombinant antigens with possible diagnostic utility are 18-kDa ribonuclease (RNU), 360-kDa catalase, and 88-kDa dipeptidylpeptidase V (DPPV). In aspergilloma patients, all three of the antigens were equally useful for diagnosis but only catalase was found to be useful in both immunocompetent and immunocompromised patients.

Galactomannan Antigen

Galactomannan (GM) is a major cell wall component of *Aspergillus*, and it is known that the highest concentrations of GM are released in the terminal phases of the disease.[100] An ELISA technique was introduced using a rat anti-GM monoclonal antibody, EB-A2, which recognizes the (1→5)-β-D-galactofuranoside side chains of the GM molecule.[107] A sandwich ELISA technique was introduced in 1995[173]; and by using the same antibody as both a capture and detector antibody in the sandwich ELISA (Platelia *Aspergillus*, BioRad), the threshold for detection can be lowered to 1 ng/mL. This technique is employed in the currently commercially available GM assay for diagnosis of IA.

Positive assay results are suggestive of invasive disease, and a 3-year prospective trial showed the sensitivity of serial monitoring was 90 percent, the specificity was 98 percent, and the negative predictive value was 98 percent. All 30 patients with proven IA tested positive, with no false-negative results. GM detection preceded the development of infiltrates on a chest radiograph in 68 percent of patients. The false-positive rate was 14 percent, and therefore the improved sensitivity over latex agglutination is counterbalanced by the loss of specificity and greater false-positive results.[108] Other studies have reported false-positive results of 5 to 8 percent and suggested they were due to cytotoxic agents, increased resorption of GM, or cross-reacting factors from the intestines.[185] In a meta-analysis conducted to characterize the clinical utility of GM assay, 27 studies from 1996 to February 28, 2005, were identified and overall the GM assay had a sensitivity of 71 percent and a specificity of 89 percent for proven cases of IA as defined by the specific clinical criteria.[143] Of note, there was considerable heterogeneity among the studies, and in subgroup analysis the performance of the test differed by patient population as well as by which reference diagnostic standard was utilized. In patients with hematologic malignancy or who have undergone hematopoietic transplant the assay was most useful, but in SOT recipients the sensitivity and specificity were 22 percent and 84 percent, respectively.

Serial testing at least twice a week is recommended.[39] In one study an increase in value during the first week of observation was predictive of treatment failure in allogeneic HSCT patients.[16] In a large prospective study of hematology and HSCT patients with confirmed or probable IA, GM was detected in 65 percent of patients an average of 8.4 days before positive CT scans or cultures, and it was detected in 40 percent of patients before the onset of clinical symptoms by a mean of 6.9 days. The sensitivity of GM detection in HSCT recipients was 89 percent, with a specificity of 98 percent. The test was performed easily with results available in 4 hours, and two

successive samples with elevated GM values were required for positivity.[174] One study found the sandwich ELISA had a sensitivity of 60 percent and a specificity of 82 percent.[109] Another prospective study involved 186 consecutive patients at risk for IA monitored twice weekly and yielded a sensitivity of 93 percent and specificity of 95 percent, and in most cases antigenemia was detected a median of 6 days before clinical symptoms.[107]

Unfortunately the GM assay has decreased sensitivity in the setting of a patient receiving anti-*Aspergillus* (mold-active) antifungal agents, while the specificity for detection does not change.[110] This is thought to be due to the decreased fungal burden in a patient receiving mold-active antifungal agents, and the difficulty lies in the fact that those are exactly the high-risk patients in whom the GM assay would be utilized. A subsequent study found that the GM test was best performed in patients not receiving any antifungal agents, in whom sensitivity was 89 percent versus 52 percent among patients who received empirical mold-active antifungal agents.[113]

Neutropenia also affects GM diagnosis. The GM value in patients with an absolute neutrophil count (ANC) less than 100 cells/μL and not receiving antifungal therapy was statistically higher than in those patients with an ANC greater than 100 cells/μL. However, GM values were not statistically different in patients with an ANC less than 100 cells/μL and receiving antifungal therapy versus those with an ANC greater than 100 cells/μL.[30] It is possible this neutropenia effect is due to fungal burden higher at the time of initial IA in neutropenia or that IA lesions are more extensive in the setting of neutropenia.

Although GM has been extensively validated in patients with hematologic malignancy and those who have undergone HSCT, for unclear reasons GM appears less useful in SOT recipients. A meta-analysis of serum GM studies revealed an overall sensitivity of 71 percent with a specificity of 89 percent; however, sensitivity dropped to only 22 percent in SOT recipients and rose to 82 percent in HSCT recipients.[143] In liver transplant recipients there was a high false-positivity, especially in patients with autoimmune liver disease or dialysis,[95] and in lung transplant recipients there was a greatly decreased sensitivity, perhaps owing to the pathophysiologic differences in *Aspergillus* tracheobronchitis or anastomotic disease seen in these patients.[74]

False-positive results with GM can hamper its clinical utility and are seen in patients concurrently receiving some β-lactam antibacterial agents such as piperacillin-tazobactam, amoxicillin, and amoxicillin-clavulanate. One study that evaluated these false-positive GM kinetics found a gradual increase in GM on patients receiving these β-lactam antibacterial agents and an average of 5.5 days to a negative antigen test.[8] There were numerous theories as to a supposed increased false positivity in children, ranging from *Bifidobacterium bifidum* spp. in the gut microflora that mimic the epitope recognized by the EB-A2 in the ELISA kit[117] to GM-positive infant formula used in pediatric patients.[1] We know now that false positivity is likely due to the ELISA testing itself cross reacting with specific antigens, likely not all of which have been defined, and this phenomenon appears irrespective of the patient's age. There are also questions about the GM false-negative results in some specific pediatric patients, such as those with CGD. One report details a non-neutropenic 4-year old child with CGD and IA diagnosed by lung biopsy who had persistent false-negative serum GM testing.[187]

Diagnosis of pediatric IA with a GM assay, while originally reported to be less useful due to a higher false-positive rate,[70,175] has been validated to be effective in children. A study of 64 pediatric allogeneic HSCT recipients found that, after excluding those patients receiving piperacillin-tazobactam, the false-positive rate was only 1.6 percent, leading to a specificity of 98.4 percent in this high-risk population. In that study, GM was falsely positive for the first sample obtained after initiation of piperacillin-tazobactam but the cessation of piperacillin-tazobactam resulted in a negative test in the immediate subsequent samples obtained (range, 3 to 4 days).[165] A subsequent report on 56 pediatric oncology patients found a pediatric sensitivity of 66 percent with a specificity of 87 percent, and in 6 of 7 cases of IA the GM test was positive before clinical or radiographic evidence of disease.[67] A retrospective study reported a similarly low false-positive rate (1.5%) and found that the GM test performed better in periods after aggressive chemotherapy than in those after allogeneic HSCT.[25]

Bronchoalveolar Lavage

Bronchoalveolar lavage (BAL) is often useful in diagnosing IA, but a negative BAL culture does not conclusively rule out disease. In one study, the BAL fluid was analyzed in 23 consecutive patients with histologically proven IA and only 7 patients (30%) had BAL specimens diagnostic for IA. In the group in whom it was diagnostic, 71 percent had multiple changes on thoracic CT, compared with 25 percent of patients with negative BAL specimens. The diagnostic yield of BAL culture was not associated with clinical symptoms or duration of neutropenia. A thorough review of the diagnostic yield of BAL specimens in histologically proven IA patients yielded sensitivities of approximately 40 percent (range, 0 to 67%)[147]; but in one study, BAL had a sensitivity of only 50 percent even in patients with focal IA.[116] The sensitivity of respiratory tract culture specimens in general has ranged from 15 to 69 percent,[141] and in one study it increased to 50 to 70 percent in high-risk IA groups.

However, the sensitivity of BAL samples may be increased by use of the GM test, thus increasing the yield of bronchoscopy and possibly avoiding the need for further invasive procedures. Although the GM test cutoff value in sera is 0.5, it is better to use a value of 1.0 for BAL fluid GM testing. A retrospective analysis of 99 high-risk hematology patients, including 58 with IA, who underwent BAL for the diagnosis of new pulmonary infiltrates found that a BAL GM test value of 1.0 or higher yielded an increased sensitivity (91.3%) compared with BAL culture (50%) or BAL microscopy (53.3%). The combined sensitivity of all three BAL methodologies was 98.2 percent.[106] Further analyses in that study found that

the mean BAL GM result was not different in neutropenic versus non-neutropenic patients.

A meta-analysis of BAL GM studies found sensitivities to be between 59 and 100 percent and specificities to be between 76 and 100 percent and most importantly that antifungal therapy did not significantly affect sensitivity, as it does with serum GM.[64] A retrospective study in patients with hematologic malignancies and in HSCT recipients also found that the BAL GM test was more sensitive than a serum GM test for diagnosing IA and found that BAL GM was not impacted by mold-active antifungal agents, suggesting that this may be due to the levels of antifungal agents found in sera versus alveolar fluid. This study supported the use of BAL GM to diagnose IA, optimizing the positive predictive value of BAL GM, whereas serum GM might be best utilized as a screening test, with the lower cutoff value used to maximize the negative predictive value.[128] A retrospective pediatric BAL GM found an optimal BAL GM cutoff value of 0.98 to yield the best sensitivity (78%) and specificity (92%). Using a BAL GM value of 1.0 or higher and a concurrent serum GM of 0.5 or higher yielded the best sensitivity (89%) and specificity (90%).[44]

(1→3)-β-D-Glucan

(1→3)-β-D-Glucan is an integral cell wall component and, in contrast to GM, is not normally released from the fungal cell.[100] Factor G, a coagulation factor of the horseshoe crab, is a highly sensitive natural detector of (1→3)-β-D-glucan.[132] The "G test" detects (1→3)-β-D-glucan via a modified limulus endotoxin assay and detects *Aspergillus*, *Candida*, and even *Cryptococcus* but does not identify the genus of the fungi detected.[132] The G test is widely used in Japan, but these tests yield positive results only at advanced stages of infection in a majority of patients.[83] A 1-year prospective study of patients with hematologic malignancy and control subjects found the sensitivity of real-time polymerase chain reaction (PCR) assay was 79 percent, that for GM was 58 percent, and that for the G test was 67 percent, with specificities of 92 percent, 97 percent, and 84 percent, respectively.[82] Currently the (1→3)-β-D-glucan assay is available in the United States as the Fungitell assay.

In a study comparing (1→3)-β-D-glucan and GM, the sensitivity, specificity, and positive and negative predictive values for GM and (1→3)-β-D-glucan were identical. False-positive reactions occurred at a rate of 10.3 percent in tests using both substances, but the patients showing false-positive results were different in each test. Both tests anticipated the clinical diagnosis and CT abnormalities, but (1→3)-β-D-glucan tended to become positive earlier than GM. A combination of the two tests improved the specificity (to 100%) and positive predictive value (to 100%) of each individual test without affecting the sensitivity and negative predictive values.[139] Another study compared GM, PCR, and (1→3)-β-D-glucan assays on patients with hematologic disorders, and the receiver-operating characteristic (ROC) analysis showed an area under the ROC curve was greatest for the GM assay, using two consecutive positive results. This suggests that the GM test was the most sensitive at predicting the diagnosis of IA in high-risk patients with hematologic disorders.[87] A meta-analysis of cohort studies of (1→3)-β-D-glucan for IA revealed that using a single test resulted in a pooled sensitivity of 57 percent with a specificity of 97 percent.[96]

Polymerase Chain Reaction Assay

Although GM assays created a noninvasive test with improved sensitivity and specificity, more recent efforts have focused on defining an optimal primer sequence for a PCR detection method. At present, this diagnostic method is not commercially available and reports can be difficult to interpret owing to the lack of experimental standardization between centers. Because of the ubiquitous nature of the mold, it is likely the value of this test will be its high negative predictive value. Issues remaining unresolved in the use of the PCR assay are the best source of material (e.g., whole blood, serum, plasma, BAL specimens), the amplification protocol (e.g., real time, sample volume, extraction methods), and primer selection (e.g., "panfungal," 18S rRNA, 28S rRNA, mitochondrial DNA).[90]

Reported sensitivities in numerous retrospective reports of PCR are 55 to 100 percent, with negative predictive values generally around 100 percent.[146] The high negative predictive value is consistent with PCR as a sensitive marker for any colonizing or infected aspergilli, and a negative PCR assay finding in a patient with a suspected IA most likely shows that the patient does not have the organism.[145] In a 2-year prospective study of 121 patients with hematologic malignancies analyzed twice weekly by screening of whole-blood samples, the negative predictive value of two or three consecutive positive PCR results was 98 percent, with a sensitivity of 75 percent and a specificity of 96 percent. When PCR was detected only once, it was never associated with disease and resolved without antifungal treatment, thus indicating only a transient *Aspergillus* DNAemia.[98]

In another prospective PCR study in 84 allogeneic HSCT patients, all patients with proven or probable IA were PCR positive and PCR was found to be the earliest indicator for patients with new-onset IA, preceding the first clinical signs by a median of 2 days and preceding the diagnosis based on typical radiographic findings by a median of 9 days. For patients without a history of IA who tested positive PCR twice, sensitivity was 100 percent and the negative predictive value was 100 percent.[68] In another study in patients with IA diagnosed by a positive PCR assay, the positive findings preceded radiologic signs by a median of 4 days. Additionally, the disappearance of fungal DNA correlated with successful therapy and post mortem the patients remained PCR positive.[50] In one study, PCR positivity preceded radiologic diagnosis in 11 of 18 patients and an ELISA did not precede a positive PCR result on any patient. The PCR assay was more sensitive than the ELISA, although the ELISA had no false-positive results.[201] Early PCR testing in children has yielded mixed results,[6] but the future will likely hold some combined use of the GM and PCR assays.

The PCR assay has been used to detect *Aspergillus* in BAL specimens, but it does not allow distinction between colonization and invasive disease. A prospective evaluation of 197 BAL samples in febrile, neutropenic patients

with lung infiltrates showed all immunocompromised patients with a negative PCR had no evidence of fungal disease and only a few patients without immunocompromise showed positive results without evidence of disease. After further dividing the patients into a high-risk group (patients with acute leukemia undergoing chemotherapy), the negative predictive value was 100 percent.[20] A two-step PCR assay was shown to detect down to as little as 10 femtogram (fg) of *Aspergillus* DNA (approximately 5 CFU/mL) and was tested in 100 consecutive patients by BAL and 278 consecutive patient blood samples. The BAL PCR test was positive in 17 immunocompromised patients, with a specificity of 93 percent and negative predictive value of 100 percent. In comparison, in the blood samples, sensitivity was only 20 percent but negative predictive value was 100 percent.[19]

TREATMENT

Overall success treating IA is dependent on numerous factors, not simply the choice of a specific antifungal therapy. As with all immunocompromised patients, detailed knowledge of host factors, underlying disease, concomitant infections, and degree and duration of immunosuppression are key. It is well known that immune reconstitution is paramount to successful IA therapy, and continued exposure to certain immunosuppressive medications, such as corticosteroids, is known to worsen IA. Any antifungal prophylaxis used before the diagnosis of IA could also have an effect on the ultimate choice of targeted therapy. Although the diagnostic workup needs to be aggressive, it should never delay antifungal therapy in the setting of true concern for IA. As such, the cornerstone of antifungal therapy for IA is prompt and aggressive institution of antifungal therapy, based on diagnostic tools but also on clinical suggestion of infection. Antifungal resistance is slowly and steadily increasing among *Aspergillus* isolates and continues to have specific geographic trends that could influence the choice of antifungal agent. There is also the question of using antifungal monotherapy or combination antifungal therapy and, if so, which classes of agents. Finally, although immune reconstitution is paramount, the role, and real benefit, of adjunctive immunotherapy remains somewhat unclear.

Since its initial approval for use in 1958, amphotericin B deoxycholate was the first line therapy of IA and the gold standard against which other therapies were measured. However, with overall survival rates of around 35 percent among patients treated with amphotericin B for several decades, in addition to limited tolerance as a result of acute and chronic toxicities, there was a clear need to develop a better antifungal agent. Although itraconazole became available in 1990 for the treatment of IA, it was not without flaws; most prominent among these were decreased fungicidal activity compared with amphotericin B, unpredictable bioavailability in the capsular formulation in high-risk patients, and significant drug interactions.[168] The next step taken in the search of a better antifungal agent was the development of three different lipid formulations of amphotericin B whose advantages included an increased daily dose of the parent drug, high tissue concentrations with better delivery to reticuloendothelial organs, decreased infusion-related side effects, and decreased renal toxicity.[45] These three lipid formulations, amphotericin B lipid complex, amphotericin B colloidal dispersion, and liposomal amphotericin B, allowed greater safety in patients who could not tolerate conventional amphotericin B.[168] A study to determine if lipid formulations are better than conventional amphotericin B for IA, while informative, may not ever take place, owing to the introduction of the second-generation triazoles and a whole new class of antifungal agents, the echinocandins.

Voriconazole is a second-generation triazole and synthetic derivative of fluconazole that was approved for use in the United States in May 2002 for therapy for IA. The global clinical trial that led to its approval was a prospective comparative study that showed that voriconazole had a superior response rate in the primary treatment of IA compared with amphotericin B—52.8 percent versus 31.6 percent, respectively. Survival rates also increased, from 57.9 percent for amphotericin B to 70.8 percent for voriconazole.[69] Although that study was criticized for employing conventional amphotericin B as the comparator to voriconazole (owing to approval indications at the time of study design), a subsequent analysis clearly showed that primary therapy with voriconazole was superior to primary therapy with amphotericin B, regardless of subsequent switching for intolerance or refractory disease to any other licensed antifungal therapies (e.g., liposomal amphotericin B, itraconazole, other agents).[138] These and other studies led to the very clear guideline recommendations of the Infectious Diseases Society of America to use voriconazole for the primary treatment of IA in all clinical sites.[191] In antifungal parlance, primary therapy is the initial treatment for IA whereas salvage therapy is therapy begun after a failure or intolerance of the primary antifungal therapy.

More recent epidemiologic studies have also shown the benefit of voriconazole versus the decades of data with amphotericin B. Controlled clinical trials have the benefit of rigorous evaluation, but they also often suffer certain biases pertaining to a generally healthier patient enrollment. A Belgian multicenter observational study observed 113 adult patients with IA and found an overall successful response rate, generally viewed in antifungal clinical trials as the sum of both the complete response and partial response rate, of 50.4 percent with voriconazole.[75] A French epidemiology study found similar results analyzing 393 adult patients with IA, concluding that any treatment regimen containing voriconazole, alone or in an antifungal combination, was superior in terms of survival to any antifungal regimen without voriconazole.[103] This improved voriconazole response rate has also translated well to the pediatric population, as shown by a review of 42 children treated for IA with voriconazole.[195] An analysis of the compassionate open-label use of voriconazole in children for refractory IA demonstrated a 43 percent complete or partial response. Voriconazole was also shown in these studies to be better tolerated and to have less toxicity than amphotericin B in both adults and children. The main side effects of voriconazole are reversible visual disturbances in up to 40 percent of patients, elevated aminotransferase levels,

and occasional skin reactions, most likely owing to photosensitization.[153]

Another new triazole is posaconazole, a derivative of itraconazole. There are no randomized studies examining posaconazole for primary therapy for IA, but numerous in vitro and in vivo data suggest that this triazole will be as effective as voriconazole as a potential first-line agent against IA. A multicenter salvage therapy study evaluated 107 patients with IA treated with posaconazole versus 86 historic controls and found a response rate of 42 percent versus 26 percent, respectively, as well as improved survival at 30 days of 74 percent versus 49 percent, respectively.[197] This study was significant because the patients were all undergoing salvage therapy (generally after failing amphotericin B products or itraconazole), demonstrating that the newer triazoles are indeed the best treatment option for IA. Additional studies support this general argument, with voriconazole or posaconazole therapy resulting in fewer deaths compared with amphotericin B products or caspofungin in an Italian study of 140 cases of IA in acute myelogenous leukemia patients[134] and with voriconazole therapy with more survivors than caspofungin, amphotericin B formulations, or itraconazole in 642 cases of IA in HSCT and SOT recipients across the United States.[9]

Although voriconazole is the clear guideline-recommended antifungal agent for primary therapy of IA, there are recommended alternatives,[191] such as liposomal amphotericin B, amphotericin B lipid complex, caspofungin, micafungin, posaconazole, or itraconazole. Because conventional amphotericin B was shown to be inferior to voriconazole, few experts recommend conventional amphotericin B for IA management but some still advocate lipid formulation amphotericin B as a potential alternative therapy, generally in the setting of prior azole exposure and/or antifungal resistance. Amphotericin B has always been considered a concentration-dependent antifungal agent, and one clinical trial evaluated liposomal amphotericin B at either 3 mg/kg/day (n = 107 patients) versus 10 mg/kg/day (n = 94 patients).[32] The favorable overall responses for the lower dose (50%) and the higher dose (46%) were similar, with no demonstrable additional benefit to higher amphotericin B dosing and only higher rates of nephrotoxicity. However, although these response rates are generally similar to the favorable response seen earlier with voriconazole,[69] most of the amphotericin B responses were partial responses and not complete treatment responses, suggesting that, overall, the triazole was more effective in disease eradication.

The echinocandins have an entirely different mechanism of antifungal action and interfere with cell wall biosynthesis, compared with the second-generation triazoles, which work by inhibiting cytochrome P-450 enzymes responsible for conversion of lanosterol to sterol and thus compromising the fungal cell membrane.[198] Three compounds are currently approved in the United States: caspofungin, micafungin, and anidulafungin. Several in vitro antifungal susceptibility studies have shown the general equivalency of all three echinocandins against *Aspergillus* species.[142] The echinocandin activity against *Aspergillus* is fungistatic, as compared with the triazole fungicidal activity, and results in activity blunting the hyphal tip but not killing the organism[17] and subsequently the reporting of an in vitro minimal effective concentration (MEC) and not a minimal inhibitory concentration (MIC).[94] Caspofungin was first studied an open-label, noncomparative salvage therapy study in immunocompromised patients with proven or probable aspergillosis.[105] It produced a complete or partial response in 45 percent (37/83) of patients, which is again very significant because these were patients were either refractory or intolerant to previous antifungal therapy. This was validated by two subsequent clinical trials in which caspofungin resulted in complete resolution or stabilization of disease in 74 percent of patients (n = 31) in one trial; and in the other trial, caspofungin had an overall response rate of 56 percent (n = 32).[23,182] Few studies have evaluated caspofungin as primary therapy for IA. One phase 2 dose-escalation clinical trial evaluated 46 patients with caspofungin as primary therapy and found a favorable response rate of 54.3 percent, but there was no dose-dependent effect on efficacy for caspofungin.[33] A more recent observational study of caspofungin as primary or salvage therapy, and as monotherapy or in a combination approach, found an overall 56.4 percent favorable response, validating caspofungin as a viable therapeutic option.[104]

The largest study with micafungin was a noncomparative, open-label, multicenter study in adult and pediatric patients to examine the safety and efficacy of micafungin in the treatment those patients with IA who had failed to respond to prior therapy or could not tolerate other therapy. Of the 225 patients who met diagnostic criteria, a favorable response rate occurred in 35.6 percent (80/225), and of those treated with only micafungin, a favorable response was seen in 6/12 (50%) of the primary and 9/22 (40.9%) of the salvage therapy group.[41] Anidulafungin has been approved in the United States for treatment of candidemia and esophageal candidiasis; and although in vitro studies show activity against *Aspergillus* species isolates, there are no clinical studies against IA as primary or salvage monotherapy.

Although voriconazole is the guideline-recommended first-line agent for primary therapy for IA, it is not completely clear when the alternative agents, such as amphotericin B lipid formulations or echinocandins or the other triazoles (posaconazole or itraconazole), should be used in place of voriconazole. The most common reason for using an alternative agent is refractory disease after primary antifungal therapy and the need to move to salvage therapy. However, it is important to first allow the primary antifungal agent adequate time for clinical effect, without continuing the use of an ineffective agent for too long in a severely ill patient. In a clinically refractory setting, it is also paramount to confirm the correct diagnosis of IA if that has not been established. For example, because mucormycosis and aspergillosis appear radiographically similar, treatment of mucormycosis with voriconazole will not result in success. Assuming that the diagnosis of IA is correct, the first step in refractory disease should be to establish that the correct dose of voriconazole is being utilized, which is especially important in children because the fundamental

pharmacokinetics of voriconazole are different in children (linear) than in adults (nonlinear).[194] For instance, although the recommended starting dose of voriconazole in adult patients is 6 mg/kg/dose twice daily for the first day and then a maintenance dosing of 4 mg/kg/dose twice daily, the preferred pediatric dosing is substantially higher. Population pharmacokinetic analyses of voriconazole in children, adolescents, and adults reveal that, based on the area under the concentration-time curve, children should be given an intravenous 9 mg/kg/dose loading dose to be comparable to the 6 mg/kg/dose given to adults.[52] Maintenance intravenous dosing in children at 8 mg/kg/dose was comparable to 4 mg/kg/dose in adults, and the oral dosing of 9 mg/kg/dose was found to be similar to adults receiving 200 mg oral voriconazole twice daily. The majority of adolescents can be dosed as adults, but in those younger adolescents (ages 12 to 14), the analysis found that body weight was more important than age in predicting voriconazole pharmacokinetics in this age. Therefore, during this age transition period, adolescents aged 12 to 14 years old should be dosed as children if their weight is less than 50 kg and dosed as adults if their weight is 50 kg or more.[52] Additionally, the oral bioavailability of voriconazole, while believed to be greater than 95 percent in adults, is lower in children at 50 to 65 percent.[84,193] This is very important, especially for those patients receiving oral voriconazole long after a transplant and during the second bimodal peak of disease at approximately day 100 after transplantation. However, even with these dosing increases, there are still suggestions of the need for higher voriconazole doses. A population pharmacokinetic analysis in adult patients found that higher voriconazole doses were required to achieve adequate therapeutic serum levels.[137]

The triazole antifungal agents require therapeutic drug monitoring. Effective management of IA requires obtaining a voriconazole trough level, which is well known to have high interpatient variability, limiting its extrapolation to a larger population, but much lower intrapatient variability, allowing successive trough levels to be used to monitor dose adjustments in the individual patient.[164] The exact voriconazole trough level for clinical efficacy against IA is unknown, because there have been several clinical studies in which occasional individual patients have had undetectable voriconazole levels and still shown a clinical response. However, it is commonly believed that a serum trough level at least greater than the usual MIC of the infecting *Aspergillus* species would be preferable. Although individual studies have debated the exact cutoff, what is clear is that the serum level should be a true trough level and not a random drug level. Most experts today would advocate for a serum trough voriconazole level of at least greater than 1.0 μg/mL and stress the importance of individualized therapy for each patient. Inherent in the individualized treatment approach is the understanding that different populations also metabolize voriconazole uniquely, with three major genotypes due to allelic polymorphisms in the human cytochrome P-450 isoenzymes (largely CYP2C19) responsible for voriconazole metabolism.[81] In refractory disease, after optimizing the dose of voriconazole, the most-studied antifungal agent for the treatment of IA, then refractory disease can be approached with one of two main options. The first is to change the class of antifungal agent used and treat with an echinocandin or lipid amphotericin B formulation to replace the triazole already used. This is especially important in the setting of prior azole (antifungal prophylaxis prior to diagnosis) exposure because of the potential concern for development of antifungal resistance. Itraconazole resistance was first described in 1997,[43] and antifungal resistance to echinocandins is currently largely due to researchers genetically modifying the *fks1* gene (target of echinocandins) in *A. fumigatus*.[151] However, azole resistance is now increasing in clinical strains,[21] including multiple-azole or pan-azole (voriconazole, posaconazole, itraconazole)–resistant strains. Azole resistance in *A. fumigatus* has emerged over the past decade, with a prevalence as high as 5 to 13 percent in the Netherlands and Great Britain.[73,184] The most common multiple-azole resistance mechanism consists of mutations in the *cyp51A* gene involved in ergosterol biosynthesis.[186] Additionally, some *Aspergillus* species are more likely to be inherently resistant to certain antifungal agents. For years, *A. terreus* was a recalcitrant *Aspergillus* species owing to its now well-described in vitro resistance to amphotericin B,[176] which has been confirmed in animal models.[196] A review of in vitro analyses, testing in multiple animals, and previously reported clinical cases showed near uniform failure with amphotericin B against *A. terreus*.[167] A multicenter retrospective analysis of more than 80 cases demonstrated that mortality was decreased in those patients who received voriconazole instead of amphotericin B.[166] Other studies have also shown that patients with *A. terreus* disease are more likely to be neutropenic,[66] more likely to have disseminated disease, and have a decreased response to all classes of antifungal agents compared with patients infected with *A. fumigatus*.[99]

Beyond occasional enrollment into antifungal clinical trials, there has been very little investigation into the treatment practice patterns or outcomes of pediatric IA patients. The largest analysis was a retrospective multicenter study of 139 children with IA that found that after the diagnosis of IA, 57 percent were treated with a lipid formulation of amphotericin B; however, 45.8 percent received three or more concomitant antifungal agents.[22] A total of 52.5 percent (73 of 139) of the patients died during treatment for IA, and immune reconstitution, rather than a specific antifungal therapy, was found to be the best predictor of survival.

Combination Antifungal Therapy for Invasive Aspergillosis

Although no controlled clinical trial fully supports it use and the efficacy of combination therapy for IA has not been conclusively established and is not guideline recommended, clinicians are desperately seeking new strategies for improved outcome. With the surge in the development of newer antifungal agents for IA, there are now more permutations of new potential combination antifungal therapies. Drawing from other infectious diseases such as HIV infection, tuberculosis, and cryptococcal meningitis,[13] combination therapy for IA seems plausible

to optimize therapy. Unfortunately, the range of in vitro, animal model, and small clinical series data extend from synergy to antagonism and actually parallel the wide range of unproven treatment practices used by clinicians today searching for the best care for their patients.

The largest analysis of combination therapy for IA reviewed 6281 total cases of IA management from 1966 through 2001, focusing on 249 clinical combination reports in 128 clinical articles.[169] Unfortunately, three combination regimens that are not commonly used now nor currently recommended (amphotericin B + flucytosine, amphotericin B + itraconazole, and amphotericin B + rifampin) comprised the majority of reported clinical experience at that time. Although these data helped lay the foundation of combination therapy in the past, the combinations used historically are not necessarily the combinations considered by today's clinician.

There are several foreseeable advantages to combination antifungal therapy: a widened spectrum and potency of drug activity, more rapid antifungal effect, synergy, lowered dosing of toxic drugs, and a reduced risk for antifungal resistance.[101] Although each individual antifungal agent has limitations, combinations might prove more effective, as seen with the now standard highly active antiretroviral therapy (HAART) used with HIV-infected patients. Absent large-scale clinical trials, clinicians often derive treatment strategy information from experimental in vitro or in vivo data. Unfortunately, because of the extensive heterogeneity of both experimentation and interpretation, one cannot accurately draw a firm conclusion as to the clinical relevance of the experimental combination antifungal experiments. Perhaps the greatest usefulness for in vitro combination is to screen antagonistic interactions before investigating animal model or clinical studies.

Animal model testing is therefore preferred over in vitro analysis because of greater predictive value for human pharmacokinetic and pharmacodynamic effects, including tissue penetration and achievable drug levels at the foci of infection and toxicities. In vivo testing can also compare various disease location models and analyze different host immune states. In addition, histologic examination can examine fungal sterilization. Although in vitro testing might suggest an effective antifungal agent, the dose needed to achieve the desired effect might be unachievable safely in vivo or the drug may not penetrate infected tissue adequately.

In the simplest terms, for combination antifungal therapy to be viable, the combination treatment would need to be superior to any of the individual therapies. The advent of voriconazole has made this task more complicated because the agent is quite effective at killing *Aspergillus*, sterilizing infected animal tissue in numerous animal models, and clinically curing patients who were once thought hopeless. Regardless of the continuous stream of data, the in vitro and in vivo interactions must continue to be questioned because of so many confounding patient variables, leaving clinical experience still the most accurate tool. However, clinical relevance might best be related to patient factors (e.g., recovery of neutropenia, cessation of glucocorticoid therapy) and not intrinsically related to the susceptibility of the fungus itself.

Combination in vitro testing has many potential pitfalls, and the final fractional inhibitory concentration index (FICI) itself, the mathematical foundation behind the commonly used checkerboard test, can also be clinically deceiving. For example, in one study the interaction between fluconazole and terbinafine was reported to be synergistic against *A. fumigatus* strains (FICI 0.38).[121] However, individually fluconazole is well known to have zero anti-*Aspergillus* activity and terbinafine has poor tissue penetrance[72] and would be a likely poor clinical choice for IA. Not surprisingly, the individual MIC of fluconazole was 512 μg/mL and that of terbinafine was 8 μg/mL, yet both did improve when in combination to 64 μg/mL and 2 μg/mL, respectively, therefore mathematically achieving the definition of antifungal synergy. However, one could argue that this result only indicates that two already poor choices for treatment were simply made less poor in combination. It is unlikely clinicians would advocate combination therapy with fluconazole and terbinafine for their IA patients despite a final result of "synergy" based on in vitro testing.

Although in vitro combination studies have inherent experimental variations, there is likewise no standardization in animal model experimentation. It has been suggested that if a single antifungal agent offers as much as 50 percent protection or many infected control animals survive, it is difficult to show improvement with combination therapy over single agents.[61] Many variables influence outcome in animal model experiments similar to patient cases, including the degree of neutropenia, route of infection determining which target organs are infected, timing of drug delivery, and tissue processing and fungal burden measurement.

Although it is impossible to review all previous animal model studies of IA, the most often quoted in vivo combination antifungal model study examined voriconazole + caspofungin.[89] In this immunosuppressed guinea pig model of intravenously inoculated IA, treatment with amphotericin B or caspofungin 1 mg/kg/day or 2.5 mg/kg/day resulted in 30 to 50 percent mortality. However, treatment with voriconazole 5 mg/kg/day or voriconazole plus either caspofungin dose resulted in no mortality (0/12 in all experimental arms). Although this report helped ignite excitement about this particular combination, this guinea pig model actually showed no difference in mortality (0/12) or mean times of survival (8 days post infection) in the combination therapy arm compared with voriconazole monotherapy. Semi-quantitative organ cultures for fungal burden (colony-forming units per gram of tissue) from the liver, lung, kidney, and brain in the combinations were better than untreated controls ($p < .0025$), but there is no report of any difference between the combinations and the voriconazole monotherapy. Treatment with the combinations was significantly more effective than any of the other regimens in reducing the number of positive organ cultures compared with untreated controls ($p < .0025$), but again there was no report of any differences compared with voriconazole monotherapy. The voriconazole + caspofungin 1 mg/kg/day trial arm yielded 17 percent (8/48) positive cultures, whereas the voriconazole + caspofungin 2.5 mg/kg/day trial arm yielded 24 percent (11/48) positive cultures and

the voriconazole monotherapy arm yielded 52 percent (25/48) positive cultures.

In the clinical setting, the antifungal combination of voriconazole + caspofungin has the most anecdotal clinical experience. This is likely due to both approval and availability, as well as the presumed synergistic interaction due to the simultaneous inhibition of (1→3)-β-D-glucan synthesis in the fungal cell wall and ergosterol synthesis in the fungal cell membrane.[89,140] One pivotal study analyzed voriconazole + caspofungin as a retrospective review of 47 patients with proven or probable IA from 1997 through 2001 who experienced failure of primary therapy with amphotericin B formulations.[112] Salvage therapy was begun with voriconazole (n = 31) versus voriconazole + caspofungin (n = 16) after 7 or more days of failed amphotericin B therapy. The overall survival rate 3 months after the day of diagnosis of IA was slightly higher among those who received combination therapy (p = .048). In the bivariable analysis (controlling for antifungal therapy and receipt of HSCT), the combination showed an improved 3-month overall survival rate (hazard ratio, 0.27; 95% CI, 0.09 to 0.78; p = .008). An accompanying editorial to this article pointed out the preclinical data with combination therapy seem promising yet inconsistent.[189] The authors responded,[26] and in analyzing the patients at 1 year they found there was no difference in overall survival (p = .26).

Similar to the in vitro and animal models experiences, it is impossible to review all combination clinical studies (many as smaller and uncontrolled case series). All ranges of combinations have been reported, and results have again spanned the spectrum from an increased effect to a worsening of outcome. The obvious vast clinical heterogeneity of these reports limits direct cross-study comparisons. The prevailing expert opinion is that if a combination antifungal therapy approach is beneficial to treating IA, it is likely best taken with the combination of a cell membrane–active triazole with a cell wall–active echinocandin. A recently completed multi-national randomized clinical trial comparing voriconazole with and without the echinocandin anidulafungin showed no clear benefit of primary combination antifungal therapy for IA, and only statistical trends in improvement in certain groups.[114a] The results of a large clinical trial of voriconazole + anidulafungin versus voriconazole alone are pending, but it is unclear if any combination therapy will have the great advance that was achieved with voriconazole versus conventional amphotericin B, owing to the ever-increasing fragility of our most immunosuppressed patients with IA. Although the latest treatment guidelines state that primary combination antifungal therapy is not routinely recommended based on a lack of definitive clinical data, one retrospective study used voriconazole + caspofungin primary combination therapy in lung transplant recipients because of the known delay in time to achieve an adequate voriconazole serum level, thereby using the second agent only during those initial early weeks of therapy.[178] Other interventional therapies used in the treatment of IA include growth factors, such as granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor, granulocyte transfusions, interferon-γ, and surgery. Granulocyte colony-stimulating factor increases the number of circulating polymorphonuclear leukocytes and enhances phagocytic activity and oxidative burst metabolism. Interferon-γ promotes tumor necrosis factor-α production and enhances polymorphonuclear leukocytes and mononuclear cell–induced damage. It has been proven to help prevent IA in patients with CGD and is used as prophylactic therapy in these patients.[168] General expert opinion is that neutropenic patients with IA may benefit from the addition of a colony-stimulating factor, or possibly granulocyte transfusions, but there are limited data on efficacy.

Optimal duration of therapy in IA is unknown but likely depends on the immune status of the patient. Many experts believe that treatment should continue until complete clinical and radiographic resolution of disease, often with accompanying significant decrease in biomarkers (e.g., GM). If a patient remains substantially chronically immunosuppressed owing to ongoing cytotoxic chemotherapy or lack of engraftment after HSCT, it is advisable to continue the antifungal therapy for IA until there is no evidence of disease, often 3 months or longer. Surgical therapy may be useful in patients with lesions contiguous with the great vessels of pericardium to avoid fatal hemoptysis, but surgery to debulk disseminated lesions is generally not advised.

ABPA is a hypersensitivity disease, and therefore therapy against ABPA centers on corticosteroids to manage the allergic component of *Aspergillus*, coupled with adjunctive oral antifungal therapy to diminish the fungal burden. Itraconazole has been the most well-studied antifungal agents against ABPA, and clinical trials have shown a clear benefit in itraconazole against ABPA, including patients with cystic fibrosis and ABPA.[163] Single aspergillomas should be managed to prevent life-threatening hemoptysis, and surgical resection, if technically possible, is ideal. Medical therapy has limited utility in the treatment of aspergilloma yet is required in chronic cavitary pulmonary aspergillosis and often lifelong.

CHAPTER 198

Blastomycosis

Gregory M. Gauthier • Bruce S. Klein

Blastomyces dermatitidis, the etiologic agent of blastomycosis, belongs to a group of ascomycete fungi that exhibit thermal dimorphism. These pathogens include *Histoplasma capsulatum*, *Coccidioides immitis*, *Coccidioides posadasii*, *Paracoccidioides brasiliensis*, *Sporothrix schenckii*, and *Penicillium marneffei*. In the soil (at 22° C to 25° C), these fungi grow as filamentous mold that produce infectious conidia (asexual spores). After disruption of soil by activities such as construction, conidia and mold fragments that are aerosolized and inhaled into the lungs of the host (37° C) convert into pathogenic yeast. In the yeast form, *B. dermatitidis* can evade immune defenses by impairing the host's cytokine response. In 25 to 40 percent of patients, infection disseminates to other organs such as the skin or bone. Diagnosis requires a high degree of clinical suspicion coupled with the use of culture and nonculture diagnostic tests. Treatment recommendations, which were updated in 2008 by the Infectious Diseases Society of America, include the use of polyene or azole antifungal agents. Echinocandins are not effective. Selection of anti-infective therapy is influenced by disease severity, site of infection, and immunosuppression.

HISTORICAL PERSPECTIVE

Blastomycosis was first described as "protozoan dermatitis" by Thomas Casper Gilchrist at the 1894 American Dermatological Association meeting in Washington, D.C.[49] Two years later, Dr. Gilchrist published a detailed histologic analysis of the cutaneous findings in a manuscript titled "A case of blastomycetic dermatitis in man."[50] In 1896 and 1898, Drs. Gilchrist and W.R. Stokes described a second case of blastomycetic dermatitis and named the pathologic agent as *Blastomyces dermatitidis*.[51,52] Nearly a decade later in 1907, Walter W. Hamburger analyzed four clinical isolates and described the growth of *B. dermatitidis* as mold at room temperature and as budding yeast at 37° C.[60] During this time, heightened awareness of the disease resulted in the publication of several case reports and case series describing the clinical characteristics of blastomycosis, including invasive disease.[95,121] The majority of the clinical cases were from the Chicago area, and the disease became known as "Chicago disease" or "Gilchrist disease." In these early publications, two distinct forms of the disease were recognized: cutaneous and systemic.[95,121] In the early 1950s, Drs. Jan Schwarz and Gerald L. Baum performed a detailed clinicopathologic analysis of patients with blastomycosis and established that the primary portal of entry for *B. dermatitidis* was pulmonary and most cutaneous lesions were the result of dissemination from the lungs.[118] In the mid 1980s *B. dermatitidis* caused an outbreak in children and was successfully isolated from the soil.[74] In 2009, the genome of *B. dermatitidis* (strain SLH14081) was sequenced and annotated by the Broad Institute.[18] Genome sequencing of additional *B. dermatitidis* strains along with deep RNA sequencing to characterize the transcriptome is ongoing.

MYCOLOGY

Blastomyces dermatitidis, the etiologic agent of blastomycosis, is a haploid ascomycete fungus that exhibits thermal dimorphism by growing as yeast at 37° C and as mold at 22° to 25° C (Fig. 198-1). *B. dermatitidis* yeast forms (8 to 20 μM) are characterized by a broad-based bud (4 to 5 μM) and doubly refractile cell wall.[136] This appearance is unique among the dimorphic fungi; however, giant yeast forms (28 to 40 μM) have been reported and can potentially be confused with *Coccidioides*.[137] At environmental temperature, *B. dermatitidis* grows as septate hyphae (1 to 2 μM diameter) capable of producing conidia (asexual spores).[135,136] Conidia are small (4 to 5 μM) and are oval or pyriform. Individual conidia are attached to hyphae by a short conidiophore and have the appearance of a lollipop.[135,136] Macroscopically, yeast colonies appear off-white and colonies can have a smooth or rough appearance. Mold colonies initially appear off-white or tan.[136] The morphologic characteristics for *B. dermatitidis* mold are not pathognomonic, and definitive identification requires molecular confirmation or conversion to yeast at 37° C. The conversion between mold and yeast is reversible and can be induced in the laboratory by shifting the temperature between 22° C to 25° C and 37° C.

B. dermatitidis is considered the asexual or anamorph form. In contrast, the sexual or teleomorph form is known as *Ajellomyces dermatitidis*.[90,91] In the sexual stage, *A. dermatitidis* exhibits heterothallic mating, which means that opposite mating types (+ and –) exchange genetic material to produce progeny. During mating, *A. dermatitidis* produces cleistothecia with coiled spirals that can give rise to spores known as asci. Individual asci are capable of forming hyphae with conidia (at 25° C) or converting to virulent yeast when inoculated into mice (at 37° C).[90,91] Both sexual and asexual spores, as well as mating types (+ and –), are capable of causing infection.[88,89]

The genomes of clinical and environmental *B. dermatitidis* isolates have been sequenced, annotated, and made available to the scientific community.[18] The size of the *B.*

dermatitidis genome ranges from 66 to 75 megabases (Mb) and contains 9,522 to 10,104 genes.[18] Seventeen to 19 percent of the genome is composed of coding sequences.[18]

ECOLOGY AND EPIDEMIOLOGY

B. dermatitidis is endemic to North America and is geographically restricted to the midwestern, south-central, and southeastern regions of the United States and several Canadian provinces (Saskatchewan, Manitoba, Ontario, Quebec) (Fig. 198-2A). In endemic regions, *B. dermatitidis* is not uniformly distributed but grows in an ecologic niche characterized by forested, sandy soils of acidic pH that are located near water and contain decaying vegetation or organic matter.[74] Similar to *H. capsulatum*, a related dimorphic fungus, *B. dermatitidis* can grow in bird and animal excreta. Knowledge about the niche and conditions that promote growth of the mold form has been gleaned mostly from analysis of outbreaks of blastomycosis (Table 198-1). Occupational and recreational activities associated with infection involve disruption of soil and include construction of homes or roads, boating and canoeing, fishing, exploration of beaver dams and underground forts, and use of a community compost pile (see Table 198-1).

Outside North America, blastomycosis is a rare cause of deep fungal infection, but autochthonous cases of culture-proven infections have been reported from India and 18 countries in Africa (see Fig. 198-2).[5,87,124] *B. dermatitidis* is not considered endemic to Central America, South America, Europe, Asia, or Australia. In the developing world, the ecologic niche inhabited by *B. dermatitidis* has not been identified. *B. dermatitidis* has never been isolated from soil outside North America, nor have there been human or veterinarian outbreaks to help define the geographic distribution of this pathogen in Africa or India. When compared with North American strains, African *B. dermatitidis* isolates display unique features, including decreased ability to convert to yeast after a shift in temperature from 25°C to 37°C, unique media requirements for maintenance of yeast growth in vitro, and a less antigenically complex cell surface.[68]

Our understanding of the epidemiology of blastomycosis in North America is based on retrospective studies and passive surveillance. In the endemic zone, seven states (Wisconsin, Minnesota, Michigan, Missouri, Arkansas, Louisiana, and Mississippi) and two provinces (Ontario, Manitoba) mandate reporting of new cases of *B. dermatitidis* infection. In North America, the annual incidence of blastomycosis ranges from 0.2 to 1.94 cases per 100,000 persons (Table 198-2). Several geographic areas are considered to be hyperendemic: Kenora, Ontario (117.2 human cases/100,000 population), Vilas County, Wisconsin (40.4/100,000), Eagle River, Wisconsin (101.3/100,000), Washington Parish, Louisiana (6.8/100,000), and central and south-central Mississippi (> 5/100,000) (see Table 198-2).

The true incidence of blastomycosis is likely much greater than the reported numbers. Reliable skin and serologic tests are not available, and about 50 percent of infected persons develop subclinical or asymptomatic illness.[74] Thus, epidemiologic analysis is limited to patients with clinically apparent infection that is recognized, diagnosed, and reported to public health agencies when required by law. Most epidemiologic studies show a slight male predominance for patients diagnosed with blastomycosis (see Table 198-2), which is also observed for coccidioidomycosis and histoplasmosis. Although most patients with clinical disease have normal immune function, several medical conditions are associated with the development of severe clinical disease, including immunosuppression due to solid-organ transplantation, the acquired immunodeficiency syndrome (AIDS), and

treatment with medications that block the activity of tumor necrosis factor–α (TNF-α). Most clinically recognized cases of blastomycosis are sporadic; however, 15 well-defined outbreaks have been reported in North America (see Table 198-1).

In the developing world, blastomycosis is found mainly in Africa and India.[5,124] In Africa, nearly 100 cases have been described from countries north and south of the equator [5,22,43] (see Fig. 198-2B). Only a few cases have been identified from western Africa and none from the island of Madagascar. This contrasts to *H. capsulatum* var. *duboisii*, which is endemic to western and central Africa as well as Madagascar. In India, fewer than a dozen cases have been reported. Limitations in public health infrastructure and diagnostic capabilities likely contribute to underestimation of the true incidence of disease. The clinical presentation of blastomycosis often mimics that of other pulmonary and cutaneous infections. Physicians in North America and the developing world confront a similar challenge in considering blastomycosis in the differential diagnosis, which is important for using special stains and culture media for identification.

B. dermatitidis causes disease in children with normal and impaired immune defenses. Blastomycosis is uncommon in children, with an estimated 2 to 13 percent of cases occurring in the pediatric population.* Few studies have focused solely on the pediatric population.[39,106,117,120] In these studies, the average age was 9.1 to 11.5 years, with a range of 18 days to 18 years old, and gender distribution usually had a slight male predominance.[39,77,106,117,120] Perinatal blastomycosis is rare, with only a few reported cases.[30,86,133,140] In two well-described cases, the mothers developed disseminated blastomycosis (during the first and third trimesters) and the neonates were admitted to the hospital for medical care at 18 and 21 days of life.[86,133,140] Both neonates died of respiratory failure from severe pulmonary blastomycosis.[86,133] Similar to the neonate population, blastomycosis in infants (1 to 12 months of age) is exceedingly uncommon.[30,39,92,96]

Although the majority of cases of blastomycosis are sporadic, outbreaks are common and often result in clinical disease in children. Of the 15 reported outbreaks (see Table 198-1), 12 involved pediatric patients. Collectively, the literature on pediatric blastomycosis suggests that risk for infection is due to environmental exposure and is not influenced significantly by age or gender.[128]

PATHOGENESIS

The ability to convert from mold to yeast is an essential event in the pathogenesis of *B. dermatitidis* and other dimorphic fungi. In the soil (at 22°C to 25°C), *B. dermatitidis* grows as a mold that produces infectious conidia. After disruption of soil, aerosolized conidia and mold fragments inhaled into the lungs of a human host (at 37°C) convert into pathogenic yeast.[46] Temperature is the primary environmental stimulus that promotes this morphologic switch. The phase transition is a complex event that involves global changes in transcription, metabolism, cell signaling, cell wall composition, and plasma membrane lipid content.[46]

Over the past 2 decades, the molecular tools available to genetically manipulate the dimorphic fungi have expanded and enabled the discovery of several *B. dermatitidis* genes that impact the phase transition, including *DRK1* (dimorphism regulating kinase-1) and *SREB* (siderophore biosynthesis repressor in *Blastomyces*). *DRK1* encodes a histidine kinase that regulates the conversion of mold to yeast, production of conidia, cell wall carbohydrate composition, and expression of BAD-1 (*Blastomyces* adhesion-1; formerly WI-1).[97] Genetic deletion of *DRK1* in *B. dermatitidis* and *H. capsulatum* resulted in hyphal growth at 37°C (and 22°C), reduced transcription of the essential virulence factor BAD-1, failure to produce conidia at 22°C, and decreased cell wall glucan.[97] Moreover, *B. dermatitidis* and *H. capsulatum* with reduced *DRK1* transcript were avirulent in a murine model of infection. These studies offered genetic proof that the conversion from mold to yeast is required for virulence of the dimorphic fungi. *SREB* encodes a GATA transcription factor that promotes the conversion from yeast to mold after a drop in temperature to 22°C and regulates genes involved with the biosynthesis and uptake of specialized iron-gathering molecules known as siderophores.[48] *SREB* null mutants fail to complete the phase transition to mold at 22°C and are unable to properly maintain iron homeostasis.[48]

B. dermatitidis is considered a primary fungal pathogen because it causes disease in persons with intact or impaired immune defenses. Features of this pathogen that promote its growth in human tissue include its ability to survive core human body temperature (37°C), convert to budding yeast, express yeast-phase–specific virulence factors, and evade killing by host immune cells.[16,17,41,42,97] In the yeast phase, *B. dermatitidis* upregulates the expression of an essential virulence factor, BAD-1, which encodes a 120-kDa protein that is secreted extracellularly and binds back to chitin on the fungal cell wall.[16,41,42] Bound and soluble BAD-1 bind macrophage receptors (CD14, CR3) to induce downregulation of TNF-α in transforming growth factor–β (TGF-β)–dependent and –independent manner, respectively.[16,41,42] TNF-α is a critical cytokine for host defense against *B. dermatitidis;* antibody-mediated neutralization of TNF-α results in progressive pulmonary infection in animal models.[42] Deletion of BAD-1 renders *B. dermatitidis* nonpathogenic in a murine model of pulmonary infection, indicating this yeast-phase–specific virulence factor is essential for virulence.[17] BAD-1 also facilitates adhesion of yeast to lung tissue,[17] binds exogenous calcium,[15] and impedes binding of complement (C3) to the yeast cell surface.[142]

Changes in cell wall carbohydrate composition associated with the phase transition may also contribute to virulence and immune evasion. During the conversion from mold to yeast, the amount of α-(1,3)-glucan increases and that of β-(1,3)-glucan decreases. *B. dermatitidis* mutants deficient in α-(1,3)-glucan have impaired virulence in a murine model of infection.[61] Similarly, reduction or complete loss of α-(1,3)-glucan synthase activity in *H. capsulatum* renders this dimorphic fungal pathogen avirulent.[110] The concentration of cell wall β-(1,3)-glucan drops from 40 to 50 percent in mycelia to less than 5 percent in yeast.[65] In addition, exposed β-(1,3)-glucan binds mannose-binding lectins (MBL-A and MBL-C).[75] Collectively, these events may block the recognition of *B. dermatitidis* β-(1,3)-glucan by dectin-1 receptors on innate immune cells. Moreover, the reduction of β-glucan in the yeast cell wall precludes the use of the (1,3)-β-D-glucan test for diagnosis and of echinocandins for treatment of blastomycosis.[25,54]

To combat *B. dermatitidis*, both the innate and adaptive immune responses are required, whereas humoral immunity is dispensable. After inhalation of aerosolized conidia, alveolar macrophages are capable of phagocytizing and killing a large percentage of conidia as well as inhibiting germination to yeast.[35,122,123] Neutrophils are also capable of ingesting and killing conidia.[35] Conidia that survive the initial assault by macrophages and neutrophils germinate into yeast. *B. dermatitidis* yeast forms are more difficult to kill because they fail to induce a robust oxidative response, are relatively resistant to reactive oxygen species, and suppress nitric oxide production in macrophages.[111] The adaptive immune response, which

*References 30, 38, 45, 79, 92, 96.

is coordinated by T lymphocytes, is important for controlling *B. dermatitidis* infection in a manner that requires T-helper 17 and T-helper 1 cytokine responses (i.e., interleukin-17 and interferon-γ and TNF-α, respectively) to activate macrophages to enhance fungicidal activity and promote clearance.[14,138] After infection, patients develop specific cellular immunity to *B. dermatitidis* that persists for at least 2 years.[69]

CLINICAL MANIFESTATIONS

The clinical manifestations of blastomycosis are heterogeneous and range from asymptomatic infection to acute pneumonia to disseminated disease. The lung is the primary portal of entry for aerosolized conidia and mycelial fragments after disruption of soil. After evasion of pulmonary host defenses, *B. dermatitidis* can remain localized in the lung or disseminate to other organs. Less common routes of transmission in children include direct cutaneous inoculation and inhalation of infected vaginal secretions at birth.[86,133,140,141] Definitive evidence for transplacental transmission to the fetus is lacking but is theoretically possible; *B. dermatitidis* has been isolated from placental tissue.[81] Transmission of *B. dermatitidis* through solid-organ transplantation (i.e., infected allograft) has not been reported, but this route of transmission has been described for *H. capsulatum* and *Coccidioides* species.[84] Onset of symptomatic disease occurs 3 weeks to 3½ months after exposure to *B. dermatitidis*.[73,74]

Pulmonary Disease

Acute pneumonia is the most common clinical manifestation of blastomycosis, and symptomatic disease develops in approximately 50 percent of infected children.[74] Clinical manifestations resemble community-acquired pneumonia and include fevers, chills, headache, cough (which is often productive), dyspnea, chest pain, and malaise.[39,106,128,139] Severity of disease ranges from mild illness that can be managed in the outpatient setting to acute respiratory distress syndrome (ARDS) requiring intubation and mechanical ventilation.[39,72,74,106] Chronic pneumonia can develop and is often associated with extrapulmonary dissemination and a delay in diagnosis.[39,117,120]

The lung is the most common organ affected by *B. dermatitidis* and is involved in 79 to 85 percent of patients with symptomatic blastomycosis.[39,120,139] Consolidation, which can be unilobar, multilobar, or diffuse, is the most frequent radiographic pattern described in children with pulmonary blastomycosis (Fig. 198-3).* Consolidation from blastomycosis is indistinguishable from bacterial pneumonia. Nodular and interstitial infiltrates are the second and third most common findings on chest radiography, respectively.[2,38,39,65] Hilar lymphadenopathy, pleural effusion, and lung abscess are infrequently encountered (Fig. 198-4).[2,39,72,106] Cavitary disease and mass lesions are rare in children and can mimic tuberculosis or neoplasm. After treatment of pulmonary blastomycosis, radiographic abnormalities can persist for several years and functional pulmonary deficits (i.e., restrictive or obstructive disease) can be slow to normalize in patients with severe disease.[1,2,106] Fortunately, a majority of patients experience a full recovery without long-term pulmonary sequelae.[1]

Disseminated Disease

Once infection is established in the lung, *B. dermatitidis* can disseminate to almost any organ in the body. Based

FIGURE 198-5 ■ Verrucous lesion of blastomycosis on the face of a child.

on retrospective studies, disseminated disease in children occurred in 38 to 50 percent of sporadic cases,[39,117] which is similar to adults with blastomycosis (25% to 40%).[25] In contrast, dissemination with acute pulmonary blastomycosis associated with point-source outbreaks occurred in a minority of patients.[128] The time from symptom onset to diagnosis is often delayed in patients who are diagnosed with disseminated disease.[39,117] Collectively, these data suggest that the duration of infection rather than age influences the risk for dissemination.[128]

Disseminated blastomycosis most commonly affects the skin and bone.[39,120,139] Cutaneous disease often begins as papulopustular lesions and progresses to ulcerative, verrucous, or crusted lesions (Figs. 198-5 and 198-6).[139] Erythema nodosum, which is common in patients with histoplasmosis and coccidioidomycosis, is rare in blastomycosis.[139] Skin involvement can also be associated with underlying osteomyelitis and manifests as pustules, abscesses, and ulcers (Figs. 198-7 and 198-8).[98] Invasion of *B. dermatitidis* into the bone results in lytic destruction that is often associated with a periosteal reaction and a sclerotic margin.[98] Although any bone can be infected, the most common sites include the long bones (e.g., tibia, humerus), skull, ribs, and vertebral bodies (Figs. 198-9 and 198-10).[39,98,112,120,139] Clinical manifestations of osteomyelitis include bone pain and soft tissue swelling associated with a draining sinus, ulcer, or abscess.[98] Vertebral osteomyelitis can be complicated by extension into the soft tissues resulting in paravertebral and psoas abscesses or invasion of the adjacent intervertebral discs and vertebral bodies.[112] These features can mimic *Mycobacterium* tuberculosis (Pott disease).[98] Progressive destruction of vertebral bone can result in compression fractures.[112] Similarly, osteomyelitis of the long bones can be complicated by pathologic fracture or extend into the joint space to cause septic arthritis.[77,98]

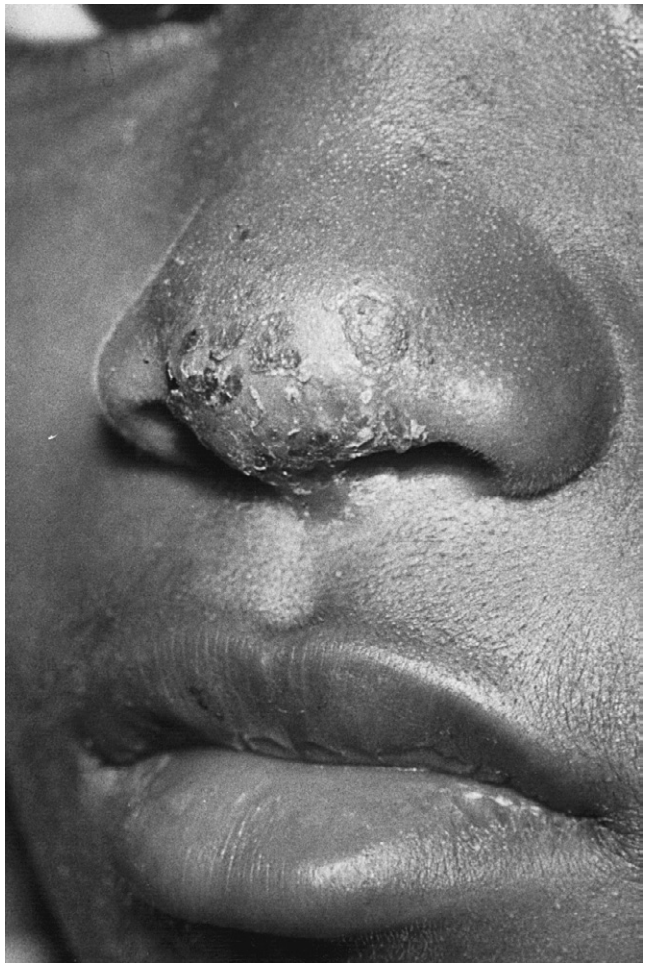

FIGURE 198-6 ■ Crusted skin lesion on the nose caused by *B. dermatitidis.*

Blastomycosis rarely disseminates to the central nervous system (CNS) or other organs such as the liver, spleen, heart, or middle ear.[62,64,139] Otitis media from blastomycosis is an uncommon complication related to contiguous extension from an extra-auditory focus into the middle ear.[40,64] CNS blastomycosis is estimated to occur in less than 5 to 10 percent of nonimmunocompromised patients and results from hematogenous spread or direct invasion from untreated infection of the scalp or skull.[39,78] CNS blastomycosis manifests as meningitis, epidural abscess, or brain abscess involving the cerebrum or cerebellum (Fig. 198-11).[9,39,78] A minority of patients can have concomitant meningitis and brain abscess.[9] Complications include hydrocephalus, mass effect from edema, cerebral herniation, infarction, seizures, panhypopituitarism, residual weakness, and impaired ability to function at school.[9,39] In patients with meningitis, cerebrospinal fluid (CSF) demonstrates a lymphocytic or neutrophilic pleocytosis associated with elevated protein and hypoglycorrhachia.[9] CSF cultures grow *B. dermatitidis* 45 percent of the time.[9]

FIGURE 198-7 ■ Purulent wound drainage overlying a region of osteomyelitis with blastomycosis.

Disease in Immunocompromised Patients

Information regarding the clinical course and treatment outcomes for blastomycosis in children with impaired immunity is limited to only a few case reports.[131,141] Clinical studies investigating blastomycosis in persons who have undergone solid-organ transplantation, developed AIDS, or been diagnosed with malignancy involve adult patients.[47,58,102,103,126] Blastomycosis is estimated to occur in less than 0.2 percent of solid-organ allograft recipients and presents 0.4 to 250 months after transplantation (near equal distribution before and after the first year of transplantation).[47,58] Infection most commonly causes pneumonia, which is often complicated by respiratory failure or ARDS.[47,58] The frequency of extrapulmonary infection (33% to 50%) is similar to that in the general population (25% to 40%).[10,47,58] Mortality ranges from 33 to 38 percent; however, it increases to 67 percent in patients with ARDS.[47,58,103]

Blastomycosis in AIDS is uncommon, and a single case series of 15 patients was published before the use of highly active antiretroviral therapy (HAART) that systemically investigated *B. dermatitidis* infection in this patient population.[102] The lung was infected in 87 percent

FIGURE 198-10 ■ MR image of the spine demonstrating signal abnormalities at T11 through L3 with a severe compression deformity of the L1 vertebral body and multiple oval lytic lesions caused by blastomycosis.

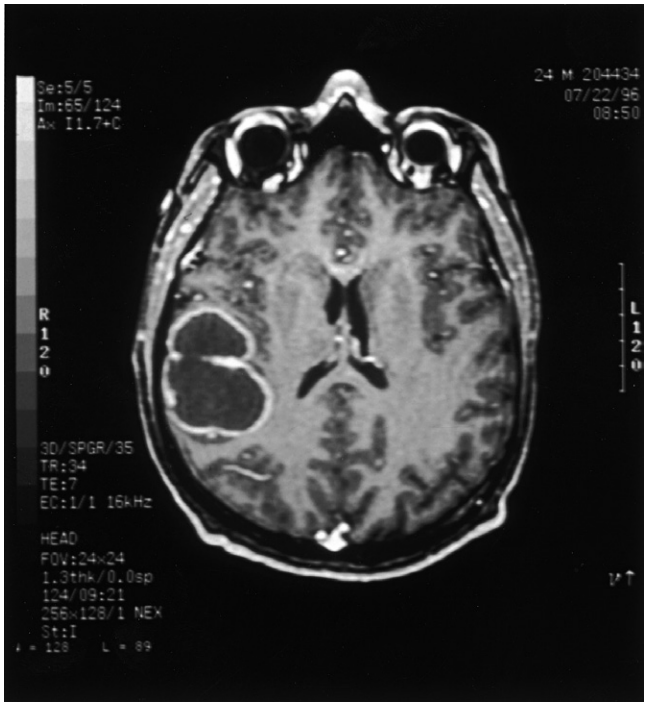

FIGURE 198-11 ■ CT scan of the brain demonstrating a multiloculated abscess in the right temporal lobe as a result of infection with *B. dermatitidis.*

of patients, and extrapulmonary disease occurred in 53 percent.[102] Invasion of *B. dermatitidis* into the CNS was common and occurred in 40 percent of patients. This is in sharp contrast to patient's immunosuppressed by transplantation or malignancy in whom the incidence of CNS blastomycosis is similar to that in the general population (<5% to 10%).[47,58,78,103] Approximately two thirds of AIDS patients with blastomycosis experienced prior opportunistic infections. The $CD4^+$ T-lymphocyte count at the time of diagnosis for blastomycosis was often less than 200 cells/mm^3.[102] Mortality attributable to blastomycosis was 53 percent.[102]

B. dermatitidis can infect patients with hematologic or solid-organ malignancies, including those with lung carcinoma, squamous cell cancers of the head and neck, breast cancer, gastrointestinal neoplasms, chronic lymphocytic leukemia, acute myelogenous leukemia, Hodgkin disease, and multiple myeloma.[103,126] Similar to allograft recipients and those with AIDS, pneumonia was the most common clinical manifestation and was complicated by ARDS in some patients.[103] Extrapulmonary disease occurred in approximately 50 percent.[103] Not surprisingly, mortality was high and was attributable to either the underlying malignancy or blastomycosis.[103]

Blastomycosis in Pregnancy and the Neonate

Blastomycosis is a rare complication of pregnancy, and clinical information is limited to sporadic case reports.[11,30,79] Women can be infected in any trimester, but the disease is most frequently diagnosed in the second or third trimester.[11,30,79] Disseminated disease is common (62%) and often involves the lungs, bone, and skin.[79] Isolated pulmonary infection occurs in less than half the patients (38%).[79] Reliable information regarding the frequency of placental involvement is lacking because examination by histology or culture has been performed in only one third of clinical cases. However, dissemination to the placenta is possible.[79,81] Histologic analysis identified *B. dermatitidis* yeast in the placenta of a 23-year-old women with

pulmonary blastomycosis complicated by ARDS during the third trimester.[81] Her infant was delivered by cesarean section and did not develop blastomycosis.[81]

Although clinical data are limited, *B. dermatitidis* infection during pregnancy does not appear to increase the risk for congenital malformations. However, based on isolation of *B. dermatitidis* from the placenta of one mother and two well-described clinical cases of neonatal blastomycosis, there is potential for transmission of blastomycosis during the peripartum period.[81,86,133] Regarding neonatal infection, both infants were admitted to the hospital for respiratory failure at 18 and 21 days of life. Infection was limited to the lungs, and both infants died of progressive pulmonary blastomycosis.[86,133] The underlying pathogenesis of neonatal blastomycosis is not well defined and may involve transplacental transmission or aspiration of infected vaginal secretions.

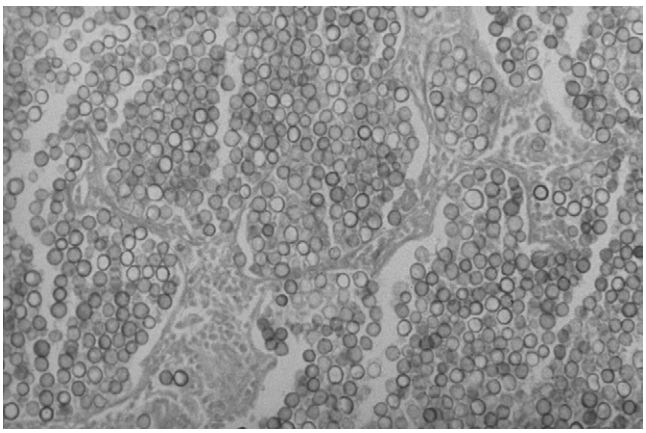

FIGURE 198-12 ■ Overwhelming infection with *B. dermatitidis* demonstrated in lung tissue with a silver stain.

DIAGNOSIS

The diagnosis of blastomycosis requires a high index of suspicion because clinical and radiographic manifestations can mimic other diseases including bacterial pneumonia, mycobacterial infections, and neoplasm. A detailed history focusing on potential exposures for the acquisition of *B. dermatitidis* can facilitate diagnosis in a timely fashion. The delay between symptom onset and diagnosis often exceeds 2 months.[39,117,120] Risks factors for endemic fungal infections include, but are not limited to, outdoor activities (i.e., canoeing, hiking, beaver dam exploration), home remodeling, construction (residential, commercial, road), playing in outdoor forts, hunting, fishing, use of a woodpile for a wood burning stove, and employment in a microbiology laboratory (see Table 198-1).[57,76] The diagnosis of blastomycosis in a household pet, frequently a dog, suggests a common source of exposure.* Thus, canine blastomycosis can serve as a harbinger of human blastomycosis.[116] Airborne transmission of *B. dermatitidis* between animals and humans does not occur; however, primary cutaneous blastomycosis has been reported from bite injuries.[55,57] Similarly, microbiology laboratory workers are at risk for cutaneous infection from injuries from sharp implements such as needlesticks.[57,76] In addition, diagnostic evaluation for blastomycosis should be considered in patients with pneumonia or cutaneous lesions that fail to respond to antibiotic therapy. The presence of pneumonia on chest radiography and cutaneous lesions on physical examination are highly suggestive of blastomycosis.

Definitive diagnosis of blastomycosis requires identification of *B. dermatitidis* in culture from sputum, skin, bone, or other clinical specimens. Commonly used culture media include Sabouraud dextrose agar and potato dextrose agar.[113] For culture of tissue specimens, supplementation of medium with brain-heart infusion agar is recommended.[113] Incubator temperatures used in most clinical laboratories (25°C to 30°C) promote the growth of *B. dermatitidis* as mold. Because several other fungal species have a similar appearance, additional confirmatory tests are required. This can include use of chemiluminescent DNA probes that target specific rRNA sequences, polymerase chain reaction assay, and conversion to yeast at 37°C.[113]

A presumptive diagnosis of blastomycosis can be made when yeast forms (8 to 20 μm) with broad-based budding and a doubly refractile cell wall are visualized by light microscopy from respiratory secretions, purulent material, or histopathologic sections. Visualization of *B. dermatitidis* requires special stains such as 10 percent potassium hydroxide, calcofluor white, Gomori methenamine silver (GMS), periodic acid–Schiff (PAS), or Papanicolaou (Fig. 198-12).[78] *B. dermatitidis* yeast can be difficult to visualize using Gram staining or hematoxylin and eosin stains. The presence of neutrophilic infiltration with noncaseating granulomas (pyogranulomas) in tissue specimens can suggest the diagnosis of blastomycosis and should prompt detailed microscopic examination for *B. dermatitidis* yeast.

For patients with pulmonary disease, specimens can be obtained from sputum, tracheal aspiration, bronchoscopy with bronchoalveolar lavage (BAL), or open-lung biopsy. Sputum cultures can be diagnostic for *B. dermatitidis* in up to 75 percent of patients[85]; however, sputum specimens tend to be more useful in older patients because collection of high-quality sputum can be difficult to obtain in young children.[117] If sputum cannot be obtained or is nondiagnostic, a tracheal aspirate or bronchoscopy with BAL can be performed. Although the diagnostic yield for BAL has been reported as 92 percent, results in the pediatric population may be suboptimal owing to technical limitations.[85,117] If specimens obtained from sputum and BAL fail to demonstrate *B. dermatitidis* and clinical suspicion remains high, then open-lung biopsy is required. In some case series,[117] but not others,[39] lung biopsy was needed for diagnosis in a majority of children.

Nonculture diagnostic techniques are often used in conjunction with fungal smear and culture to facilitate the diagnosis of blastomycosis. The development of an antigen test against a galactomannan component of the *Blastomyces* cell wall has become an important adjunctive test. Specimens for antigen testing can be collected from

*References 4, 11, 13, 19, 53, 93.

the urine, serum, BAL fluid, and CSF; however, robust clinical data exist for only urine and serum specimens.[8,29,36] Sensitivity for the urine antigen ranges from 85.1 to 92.9 percent and is influenced by the burden of infection.[8,29] In patients with localized pulmonary disease, sensitivity decreases to 50 percent, whereas in those with diffuse pulmonary disease, sensitivity increases to 87.5 percent.[9] Moreover, antigen levels tend to be higher in those with ARDS than those without.[29] Serum *Blastomyces* antigen sensitivity is 57 to 81.8 percent.[8,29] Because there is substantial cross reactivity with *H. capsulatum* (96%), *P. brasiliensis* (100%), and *P. marneffei* (70%), the specificity of the antigen test is 76.9 to 79 percent.[8,36] At times, cross reactions can cause diagnostic difficulties because *H. capsulatum* and *B. dermatitidis* exist in similar endemic regions in North America. However, this does not usually impact clinical management because treatment recommendations for blastomycosis and histoplasmosis are similar.[25,134] Diagnostic confusion related to cross reactions with *P. brasiliensis* or *P. marneffei* are uncommon, unless the patient has resided in or visited Central/South America or Southeast Asia, respectively. Urine antigen detection has been successfully used in the pediatric population for diagnosis and monitoring the response to antifungal therapy.[94]

Serologic studies such as complement fixation (CF), immunodiffusion (ID), and enzyme immunoassays (EIA) have been largely supplanted by the *Blastomyces* antigen test. Although specificity for CF and ID assays range from 97 to 100 percent, the sensitivity is 9 percent and 28 percent, respectively.[73] EIA has a sensitivity of 77 percent with a specificity of 92 percent.[73] All three serologic tests detect antibodies against the A antigen found in the *B. dermatitidis* cell wall. A radioimmunoassay against BAD-1 (formerly WI-1) has a sensitivity of 85 percent and specificity of 98 percent; however, this test is not commercially available.[71]

TREATMENT

Treatment of blastomycosis is influenced by the severity of the infection, the presence or absence of CNS dissemination, integrity of the immune system, and pregnancy (Table 198-3).[25] Antifungal therapy is recommended for all patients diagnosed with blastomycosis, including those with resolution of clinical symptoms before receiving therapy.[25] Although spontaneous resolution of symptomatic blastomycosis has been reported,[115] the frequency of this phenomenon remains unknown. Moreover, dissemination to organs such as the skin and CNS can occur after the spontaneous resolution of pulmonary disease. Because 38 and 50 percent of children with blastomycosis develop disseminated disease,[39,117] the decision to withhold therapy for pulmonary blastomycosis can be dangerous and lead to extrapulmonary spread of infection. Thus, the goal of therapy for patients with spontaneous resolution of acute pulmonary blastomycosis is to prevent extrapulmonary blastomycosis.[25]

For children with mild to moderate pulmonary blastomycosis, itraconazole 10 mg/kg/day (maximum, 400 mg/day) for 6 to 12 months of therapy is recommended (see Table 198-3).[25] For children with severe pulmonary blastomycosis including ARDS, treatment

TABLE 198-3 **Treatment of Blastomycosis in Children and Pregnant Women**

	Drug of Choice	Dose	Duration
Pulmonary Blastomycosis			
Mild to moderate	Itraconazole	10 mg/kg/day*	6–12 mo
Severe or life-threatening	Amphotericin B deoxycholate	0.7–1 mg/kg/day	1–2 wk
	Lipid amphotericin B	3–5 mg/kg/day	1–2 wk
	Itraconazole†	10 mg/kg/day*	12 mo
Extrapulmonary (non-CNS) Blastomycosis			
Mild to moderate	Itraconazole	10 mg/kg/day*	6–12 mo
Severe or life-threatening	Amphotericin B deoxycholate	0.7–1 mg/kg/day	1–2 wk
	Liposomal amphotericin B	3–5 mg/kg/day	1–2 wk
	Itraconazole†	10 mg/kg/day*	12 mo
Immunocompromised Patient	Amphotericin B deoxycholate	0.7–1 mg/kg/day	1–2 wk
	Liposomal amphotericin B	3–5 mg/kg/day	1–2 wk
	Itraconazole†	10 mg/kg/day*	12 mo
CNS Blastomycosis	Liposomal amphotericin B	5 mg/kg/day	4–6 wk
	Itraconazole‡	400–600 mg/day	12 mo
	Fluconazole‡	800 mg/day	12 mo
	Voriconazole‡	400–800 mg/day	12 mo
Pregnant Patient	Liposomal amphotericin B	3–5 mg/kg/day	
Neonate	Amphotericin B deoxycholate	1 mg/kg/day	

*Maximum dose of 400 mg/day.
†Itraconazole should be started after at least 1 to 2 weeks of therapy with amphotericin.
‡Itraconazole, fluconazole, or voriconazole should be started after at least 4 to 6 weeks of therapy with amphotericin.

consists of induction with amphotericin B for 1 to 2 weeks and consolidation with itraconazole (10 mg/kg/day; maximum, 400 mg/day) for 12 months (see Table 198-3).[25] Recommended amphotericin B formulations include amphotericin B deoxycholate (0.7 to 1 mg/kg/day) or liposomal amphotericin B (3 to 5 mg/kg/day).[25] In general, children tolerate the deoxycholate formulation better than adults.[25]

Treatment recommendations for children with impaired immunity from human immunodeficiency virus (HIV) infection or AIDS, transplantation, or malignancy involves induction therapy with amphotericin B followed by consolidation with itraconazole (see Table 198-3).[25] In some immunosuppressed patients, life-long suppression may need to be considered if immune suppression cannot be reversed.[25] Specific recommendations regarding criteria for suppressive therapy are lacking and the decision is left to the health care provider. In adults, the majority of transplant recipients adequately treated for blastomycosis do not experience relapse and life-long suppressive therapy is used only in select patients.[47,58] Whether these clinical observations in adult transplant recipients are directly applicable to immunosuppressed pediatric patients is unknown.

Children with mild to moderate disseminated blastomycosis are treated with itraconazole 10 mg/kg/day (maximum, 400 mg/day) for 6 to 12 months (see Table 198-3).[25] Patients with severe disseminated disease are treated in a similar manner as those with severe pulmonary disease. This includes induction therapy with amphotericin B for 1 to 2 weeks followed by 12 months of itraconazole.[25]

Treatment of CNS blastomycosis requires a prolonged course of liposomal amphotericin B at 5 mg/kg/day for 4 to 6 weeks followed by high-dose azole antifungal therapy for at least 12 months.[25] Liposomal amphotericin B is the preferred formulation because of its superior CNS penetration when compared with amphotericin B lipid complex (ABLC) or amphotericin B deoxycholate.[25,59] Recommended azoles include fluconazole 800 mg/day, itraconazole 200 mg two to three times a day, or voriconazole 200 to 400 mg twice a day.[25] The most effective azole for CNS disease remains to be determined. Fluconazole has excellent CSF penetration (52% to 82% of serum levels), but minimal inhibitory concentrations are higher than those with either itraconazole or voriconazole.[56,66] Itraconazole has been successfully used to treat some cases of CNS blastomycosis despite its poor penetration into the CSF at less than 10 percent.[25,66] In contrast, voriconazole levels in the CSF are 38 to 68 percent of serum and minimal inhibitory concentrations are similar to those of itraconazole.[56,66] There are several case reports of successful use of voriconazole to treat adults with CNS fungal infections including blastomycosis.[125] Surgical débridement should be considered for patients with intracranial masses, epidural abscesses, cranial osteomyelitis, and spinal osteomyelitis with instability.[132]

Pediatric patients of childbearing age with blastomycosis should undergo pregnancy testing before initiation of antifungal therapy. High-dose and prolonged treatment with triazoles increases the risk for fetal deformities and spontaneous abortion.[7,33,105,109,130] Administration of fluconazole to pregnant patients diagnosed with *Coccidioides immitis*, a dimorphic fungus related to *B. dermatitidis*, resulted in skeletal and craniofacial defects resembling Antley-Bixler syndrome.[109] Voriconazole and posaconazole can cause skeletal abnormalities in animal models.[105,130] Several human studies have demonstrated that itraconazole increases the risk for spontaneous abortion.[7,33] To minimize harm to the developing fetus, liposomal amphotericin B 3 to 5 mg/kg/day is recommended.[25,28] After delivery, the placenta should be examined histopathologically for *B. dermatitidis*. The neonate should be carefully assessed for infection and clinically monitored for the clinical signs and symptoms of blastomycosis. Amphotericin B deoxycholate 1 mg/kg/day is the recommended antifungal agent for treatment of neonatal blastomycosis.[25]

Effective clinical management of patients with blastomycosis requires efforts to minimize toxicity, avoid drug-drug interactions, optimize bioavailability, and monitor drug levels. Amphotericin B deoxycholate and its lipid formulations are fungicidal against blastomycosis and achieve high rates of clinical cure[26]; however, these agents require intravenous administration, are nephrotoxic, and promote urinary wasting of potassium, magnesium, and bicarbonate. Hydration with normal saline before and after therapy with amphotericin and use of lipid-associated formulations can minimize the risk for nephrotoxicity.[114] Replacement of potassium and magnesium losses is needed in most patients. Bicarbonate replacement is rarely required. Frequent monitoring of electrolytes and creatinine is needed for patients receiving amphotericin.[25]

In contrast to amphotericin B, azole antifungal agents are fungistatic against *B. dermatitidis* and clinical efficacy varies among the available agents. In a prospective, nonrandomized, open-label trial, itraconazole 200 to 400 mg/day resulted in a 90 percent cure rate.[34] Itraconazole is available in capsule and liquid formulations. Absorption of the capsule formulation is enhanced with gastric acidity and coadministration with food.[25,32] The liquid formulation (100 mg/10 mL) has 30 percent better bioavailability than the capsule formulation and should be administered without food.[25,32] Fluconazole is less efficacious than itraconazole and is no longer recommended by the 2008 guidelines published by the Infectious Diseases Society of America for pulmonary or non-CNS disseminated blastomycosis.[25] If fluconazole is used for treatment, 400 to 800 mg/day dosing is required to optimize clinical response. The success rate for 400 to 800 mg/day dosing was 87 percent, whereas it was 65 percent for 200 to 400 mg/day.[100,101] Approximately 50 percent of patients who received high-dose fluconazole experienced adverse events, including alopecia, xerosis, and elevated results of liver function tests.[100] Similar to fluconazole, ketoconazole is no longer recommended for the management of blastomycosis.[25] The newest triazoles, voriconazole and posaconazole, have excellent in vitro activity against *B. dermatitidis*.[56] Although clinical experience with voriconazole is limited, several case reports suggest that it can be an effective treatment option.[6,99,126] Posaconazole has demonstrated clinical efficacy in two

patients with disseminated blastomycosis.[108] To optimize bioavailability, voriconazole needs to administered in the fasting state whereas posaconazole requires coadministration with food.[105,130]

Therapeutic drug monitoring for itraconazole is recommended once steady-state levels are achieved, which is at the end of the second week of therapy. Given the long half-life of itraconazole (i.e., 24 hours), serum levels can be obtained independent of the time the drug was administered.[25] Goal therapeutic levels are more than 1 µg/mL (both itraconazole and hydroxy-itraconazole are added together).[25] Serum concentrations greater than 10 µg/mL are not needed and can increase the risk for side effects. Therapeutic drug monitoring can also be performed for voriconazole; goal serum levels are between 1.0 and 5.5 µg/mL.[3] In addition to therapeutic monitoring, liver function tests should be assessed at baseline, at 2 and 4 weeks into therapy, and then every 3 months for all azoles.[25] Moreover, careful review of all medications is needed to avoid drug-drug interactions with azoles. This is especially important for patients who are immunosuppressed by organ transplantation or receiving pharmacologic therapy for seizures.

Débridement for osteomyelitis or abscesses is not considered curative, and antifungal agents should always be administered after surgical intervention. Moreover, the duration of antifungal therapy should not be shortened.

Patients diagnosed with blastomycosis do not require isolation because person-to-person transmission through aerosols or respiratory droplets has not been reported. Standard barrier precautions (i.e., gloves) are needed in caring for patients with open wounds.

CHAPTER 199

CANDIDIASIS

Grace E. Lee • David A. Kaufman • Theoklis E. Zaoutis

Over the past 3 decades, *Candida* spp. have emerged as major fungal human pathogens, largely owing to advances in health care technology and medical therapies.[26,78,340,349] Expanding use of organ transplantation, immunomodulatory therapies, and immunosuppressive chemotherapeutic regimens, as well as broad-spectrum antimicrobial therapy and invasive devices, has contributed to a growing population of immunocompromised individuals highly susceptible to invasive fungal disease. *Candida* is the most common cause of invasive fungal infection in health care settings and is associated with significant increases in health care resource utilization and attributable mortality.[84,253,286,344] A discussion is presented of the epidemiology, pathogenesis, clinical manifestations, diagnosis, and management of candidiasis in the pediatric population. Because of notable differences in the pathogenesis, presentation, and management of invasive candidiasis in neonates, neonatal candidiasis is discussed separately later in the chapter.

THE ORGANISM

Candida spp. are a heterogeneous group of eukaryotic, diploid organisms that grow predominantly as yeast morphology (i.e., unicellular). Most members are able to produce pseudohyphae; however, only *C. albicans* and *C. dublinensis* are able to produce true hyphae, making them the only polymorphic *Candida* spp. *Candida* spp. are commensal organisms, commonly found in the gastrointestinal and genitourinary tracts of healthy humans. More than 150 species have been described; of these, at least 17 different species have been found to cause invasive disease.[118,282] *C. albicans* is the most frequent species isolated from humans; other more commonly isolated pathogenic species include *C. parapsilosis*, *C. tropicalis*, *C. glabrata* (previously known as *Torulopsis glabrata*), and *C. krusei*. Less commonly, invasive *Candida* infections (ICIs) may be due to *C. guilliermondii*, *C. lusitaniae*, *C. dublinensis*, *C. pelliculosa*, *C. kefyr*, *C. rugosa*, *C. famata*, *C. norvegensis*, *C. orthopsilosis*, *C. metapsilosis*, *C. nivariensis*, and *C. inconspicua*. Previously classified as *C. albicans*, *C. dublinensis* has only more recently been appreciated as a distinct species.[301]

Candida spp. grow well on routine agar and do not require special fungal media for isolation. The color of *Candida* colonies may vary from cream to yellow, and the texture may be smooth to wrinkled and glistening or dry, depending on the species. Under optimal growth conditions, yeast grow in log phase as unicellular budding yeast forms (blastospores) that are spherical to ovoid and measure 2.5 to 6 μm in diameter.[111,282] Pseudohyphae are polarized growths that form when budding daughter cells remain attached to the parent cell wall, forming elongated, often branching forms with constricted septal junctions between cells. In contrast, true hyphae are formed from yeast cells or as branches from existing hyphae and are characterized by defined septa that divide the hyphae into separate fungal units. As previously mentioned, true hyphae are a feature of *C. albicans* and *C. dublinensis* and grow in the presence of serum at 37° C and at pH 7.[179,282,300] Germ tube formation is a precursor to hyphae and can be induced as a test for rapid, presumptive identification of *C. albicans*, although false-positive and false-negative results may occur.[125,280] In contrast, *C. glabrata* only exists as blastoconidia (yeast).

Identification of the most common *Candida* spp. is possible based on carbohydrate assimilation and fermentation testing, in addition to morphology. Commercially available kits such as API 20C AUX, the Auxacolor2, and the Uni-Yeast Tek kit utilize changes in turbidity or the production of color through enzymatic reactions to create specific biochemical profiles that permit the rapid identification of the more common *Candida* spp.[80] The advent of chromogenic agar (e.g., CHROMagar *Candida*) that incorporates substrates linked to chemical dyes in a solid medium has been particularly advantageous in allowing presumptive identification of clinically important *Candida* spp., including *C. albicans* (green smooth colonies), *C. tropicalis* (metallic blue colonies with a pink halo), *C. krusei* (pale rose flat colonies), and *C. glabrata* (white or purple smooth glistening colonies), although misidentification of less common *Candida* spp. as *C. glabrata* has been reported.[80,125,241] Chromogenic agar permits identification in as early as 24 to 48 hours and is particularly valuable in detecting coinfection with different *Candida* spp., which ordinarily may be missed during conventional subculture on a solid medium.[80,282]

EPIDEMIOLOGY

Candida is the most important cause of fungal infection in health care settings, broadly affecting a growing population of immunocompromised patients, in addition to patients with critical illness, prematurity, or complex chronic conditions. The incidence of invasive candidiasis in the United States has risen dramatically over the past 3 decades, with rates of nosocomial bloodstream infection (BSI) due to *Candida* quadrupling between 1980 and

1989.[23] More recent data demonstrated a continued 50 percent increase in candidemia-related hospitalizations in the United States between 2000 and 2005.[349] *Candida* spp. are now the third most common cause of nosocomial BSI in children, with an incidence of 43 cases per 100,000 pediatric admissions (95% confidence interval [CI], 35 to 52 per 100,000 pediatric admissions).[341,344]

The increasing burden of invasive candidiasis is especially notable given the significant morbidity and mortality associated with candidemia. Crude mortality rates in children with candidemia have been reported to range from 10.1 to 26 percent, although the attributable mortality of candidemia in children has been estimated to be 10 percent.* Evidence of dissemination has been estimated to occur in 8.3 to 17 percent of children with candidemia,[42,76,314,346] with organ involvement most commonly occurring in the lungs (45.2% to 58%), liver (23%), kidney (16%), brain (12%), heart (8% to 22.3%), spleen (8%), and eyes (3.2 to 8%).[76,346] In addition to severe clinical outcomes, candidemia in children results in a considerable increase in health care resource utilization. A retrospective cohort study using national administrative data reported a mean 21.1 day increase in total hospital length of stay (95% CI, 14.4 to 27.8 days) and a mean $92,266 increase in total charges per hospitalization (95% CI, $65,058 to $119,474).[344]

C. albicans is the predominant *Candida* spp. colonizing the gastrointestinal and genital mucosa and can be found on the mucous membranes of 30 to 60 percent of humans.[179] Not surprisingly, *C. albicans* is the most common cause of invasive fungal disease in children. A prospective (1995-1997) observational study of candidemia involving 34 U.S. tertiary-care medical centers reported *C. albicans* as the most commonly isolated species in children younger than 13 years of age, comprising 49 percent of all pediatric isolates.[225] More recently, a prospective (2007-2011) international epidemiologic study of pediatric invasive candidiasis utilizing data from 42 sites (23 in the United States, 19 in 15 other countries), recovered *C. albicans* from 44 percent of all isolates.[296] Despite its propensity to cause severe disease, *C. albicans*–specific response rates are good, with 71 percent of pediatric patients having successful outcomes (defined as microbiologic clearance and either improvement in or complete resolution of all attributable symptoms).[296]

The incidence of *C. parapsilosis* has increased in the past few decades,[236] with it becoming the second most common species isolated from children with invasive candidiasis. Two large international prospective cohort studies have reported *C. parapsilosis* as causing 22.2 to 34 percent of invasive candidiasis/candidemia in children,[225,296] which is consistent with findings from single-center pediatric studies.[75,184,294,348] In contrast to *C. albicans* (an obligate human commensal), *C. parapsilosis* can be found in a wider variety of animals, as well as the environment.[46,203,262,293,312] However, it can also be found as part of normal human skin flora. In one study examining the density of flora at various sites of the hands of 26 healthy adult volunteers, yeasts were present in 65.4 percent of samples, with *C. parapsilosis* being the most frequently isolated.[198] Not surprisingly, carriage of *C. parapsilosis* on the hands of health care workers has been associated with nosocomial outbreaks of infection with *C. parapsilosis*, with significant implications for infection prevention and control measures.[312] Experimental animal models have demonstrated *C. parapsilosis* is associated with limited virulence compared with that of *C. albicans* and *C. tropicalis*,[335] and clinical studies also have shown higher rates of treatment success in children and reduced mortality rates in adults with *C. parapsilosis* fungemia/invasive disease compared with other *Candida* spp.[225,296]

C. glabrata and *C. krusei* are less common causes of candidemia and invasive candidiasis in children. In adults, however, *C. glabrata* is the second most common cause of invasive candidiasis.[42,126,225] Importantly, *C. glabrata* and *C. krusei* are notable for their reduced susceptibility to triazole antifungal agents. *C. krusei* is intrinsically resistant to fluconazole, although most isolates are susceptible to voriconazole.[234,235] *C. glabrata* exhibits variable susceptibility to fluconazole, with cross resistance with the extended spectrum triazoles being well described.[233]

C. tropicalis is an infrequent cause of invasive candidiasis in children and predominantly occurs in oncologic populations.[169] Data from animal models indicate that *C. tropicalis* is similar in virulence to *C. albicans*, although clinically *C. tropicalis* appears to display a higher propensity for dissemination in neutropenic hosts than *C. albicans*.[165,169] *C. lusitaniae*, *C. guilliermondii*, and *C. dublinensis* are all uncommonly found in children with invasive candidiasis.

Outside the neonatal population, data on the risk factors for the development of candidemia in children remain limited. In a single-center case-control study examining risk factors for candidemia in a children's hospital, patients were more likely to have had central venous catheters, use of topical antifungal agents before candidemia, and longer exposure to hyperalimentation compared with control subjects; however, only unadjusted analysis was performed, limiting interpretation of the results.[184] A single-center, population-based, case-control study examined risk factors for candidemia in pediatric patients admitted to a pediatric intensive care unit.[348] On multivariable analysis, receipt of vancomycin or of an antimicrobial agent with anaerobic activity for 4 or more days was independently associated with a significant increased risk for candidemia (adjusted odds ratio [OR], 6.19; 95% CI, 2.40 to 15.99; and adjusted OR, 2.03; 95% CI, 1.47 to 8.38, respectively). Other significant risk factors included malignancy (OR, 4.02; 95% CI, 1.23 to 13.11) and presence of a central venous catheter (adjusted OR, 30.45; 95% CI, 7.76 to 119.49). Receipt of hyperalimentation was found to be significantly associated with candidemia on unadjusted analysis, but the association became nonsignificant after inclusion into the multivariable model. Interestingly, although hyperalimentation was not an independent risk factor for candidemia, it was found to be a significant contributor in predicting risk for candidemia. With the use of a predictive model including vancomycin, anaerobic-spectrum antibiotics, malignancy, presence of a central venous catheter, and hyperalimentation, it was found that children with three or more risk factors had between a 10 and 46 percent predicted

*References 42, 184, 225, 296, 344, 345.

probability of developing candidemia.[348] Similar risk factors of presence of central venous catheters, arterial lines, hyperalimentation, and prolonged antibiotic exposure were identified in another study performed in a population of pediatric patients in an intensive care unit.[89]

Risk factors for disseminated candidiasis in children have been examined by several investigators.[76,88,346] In a case-control study of children with candidemia, persistently positive blood cultures for *Candida* after more than 3 days with a central venous catheter in place and associated with immunosuppression (neutropenia, use of immunosuppressant medications, or history of bone marrow transplant) were found to be independent risk factors for the development of disseminated candidiasis.[346] Another case-control study of children with candidemia identified receipt of vasopressors, prolonged candidemia (≥3 days) after central venous catheter removal, and neutropenia to be independently associated with disseminated candidiasis.[76] Similarly, in an unadjusted analysis of children hospitalized with candidemia, prolonged candidemia and presence of an immunocompromising condition were found to be associated with dissemination.[88] Risk factors for mortality among pediatric patients have also been examined, with location in a pediatric intensive care unit at the time of infection, presence of an arterial catheter, tracheal intubation, and neutropenia being significantly associated with death.[225,345] With the exception of neutropenia, these risk factors are likely markers for severe illness.

PATHOGENESIS

Pathogen Factors

The virulence of a pathogen is an important determinant of the ability of a microorganism to inflict host cell damage and cause disease. Because *C. albicans* is the most common cause of invasive candidiasis and is thought to be the most pathogenic of the *Candida* spp.,[282] virulence factors have been best studied in this species. Consequently *C. albicans* will serve as the prototype for this discussion of virulence factors, with exceptions noted for other non–*C. albicans* species when relevant. The pathogenicity of *C. albicans* is mediated by several virulence factors, including adhesion, biofilm formation, secretion of hydrolytic enzymes, and morphology switching, permitting it to become the most successful opportunistic fungal pathogen in humans.

The obligatory first step in the establishment of colonization and subsequent host invasion is the adherence of *C. albicans* to host surfaces and medical devices. Adherence is essential for initiating and maintaining a commensal relationship with the host[259] and is mediated by adhesion biomolecules present at the fungal surface that permit binding to host cells and host-cell ligands. Agglutinin-like sequence proteins (Als) are the most widely expressed adhesins in *C. albicans* and encode a group of glycosyl-phosphatidyl-inositol (GPI)–anchored proteins localized on the outer cell wall layer.[313] Among all Als proteins, Als1p, Als3p, and Als5p appear to play a major role in adherence to host cells.[313] Hyphal wall protein 1 (Hwp1p) is found exclusively at the germ tube surface and is another important adhesin, mediating tight binding to buccal epithelial cells.[292] Cell wall carbohydrates such as glycosylated mannoproteins and sialic acids may also contribute to adherence.[313] Among non–*C. albicans* species, *C. tropicalis* has been shown to also produce Als proteins while *C. glabrata* has been found to produce a group of adhesins encoded by the EPA (epithelial adhesin) gene family. Cell wall adhesin-like proteins have also been discovered in *C. parapsilosis*, although further work on the virulence associated with these proteins is limited.[282]

Biofilm formation forms an important mechanism of virulence for several *Candida* spp., including *C. albicans*, *C. parapsilosis*, *C. tropicalis*, and *C. glabrata*.[282] The capacity to establish a biofilm plays a significant role in infections involving medical devices such as central venous catheters, urinary catheters, cardiovascular devices, and prosthetic implants.[162,209] *Candida* biofilms are complex communities of yeast, pseudohyphae, and hyphae encased in a self-produced extracellular matrix. The formation, structure, and composition of the biofilm is dependent on the nature of the contact surface, environmental factors, ability to switch morphology from yeast to hyphae, and *Candida* spp.[209,282] Several studies have demonstrated that biofilm growth can dramatically enhance resistance to antifungal agents. Minimal inhibitory concentrations (MICs) of amphotericin B, flucytosine, fluconazole, itraconazole, and ketoconazole against *C. albicans* growing in biofilms have all been shown to be significantly higher (up to 2000 times higher) than the MIC in planktonic *C. albicans*.[117,170,249,307] It has been suggested that biofilm-associated *Candida* organisms acquire resistance due to low growth rate and decreased drug penetration through the matrix; however, studies have not supported these conclusions.[4,17] Instead, antifungal resistance is thought to be conferred by contact-dependent upregulation of genes encoding efflux pumps during the course of biofilm formation, although multiple mechanisms may contribute to antifungal resistance of the *Candida* biofilm.[208,248]

Production of extracellular hydrolytic enzymes is an essential aspect of the pathogenicity of *Candida* spp., facilitating tissue invasion by disruption of the host mucosal membranes and by degrading important immunologic and structural proteins, including immunoglobulin (Ig) G heavy chains, α_2-macroglobulin, β-lactoglobulin, C3 protein, lactoperoxidase, collagen, and fibronectin.[238,282] The three most important hydrolytic enzymes produced by *Candida* are the secreted aspartyl proteinases (Saps), phospholipase B enzymes, and lipases.[212,282] The Sap proteins are encoded by a family of 10 SAP genes and are considered key determinants of *Candida* virulence, with level of Sap activity in vitro appearing to correlate with the virulence of *C. albicans*, *C. tropicalis*, and *C. parapsilosis*.[212] Data are limited on the capacity of *C. glabrata* to produce proteinases.

Morphologic conversion between yeast and hyphal forms is believed to play an important role in the dissemination and tissue invasion of *C. albicans*. Initial experiments using animal models suggested that the hyphal form represented the pathogenic state of the organism,

because mutant strains lacking hyphae exhibited impaired ability to invade tissue compared with wild-type *C. albicans*.[54,182] Subsequent data demonstrating constitutively filamentous mutant strains as avirulent led to the hypothesis that it was not the morphologic form per se but the ability to undergo morphology switching that contributed to the pathogenicity of *C. albicans*.[43] More recently, a mouse model of hematogenously disseminated candidiasis using a mutant *C. albicans* strain that permitted external modulation of morphology switching demonstrated that both yeast and hyphae were important stages in the development of invasive candidiasis.[271] Seville and coworkers were able to demonstrate in a mouse model of disseminated candidiasis that mice injected with this strain under conditions permitting hyphal development succumbed to infection, whereas all those injected under conditions inhibiting the formation of hyphae survived, indicating that filamentous formation was a critical factor in pathogenicity.[271] However, fungal burdens were almost identical in animals injected with strains under hyphae-permitting and hyphae-repressing conditions, suggesting that yeast forms were important for initial extravasation and dissemination in the host. Interestingly, histopathologic examination of kidneys recovered from mice exposed to hyphae-repressing conditions revealed no significant damage despite organ invasion, with all of the invading fungal cells present only in yeast form.[271]

Host Factors

Infection due to *Candida* spp. manifests primarily as mucosal and disseminated candidiasis. The immune responses to these different compartments are distinct, as evidenced by the patterns of clinical manifestations of candidiasis in individuals with immunodeficiency affecting different aspects of the immune response. Both innate and adaptive arms of the immune system play key roles in the immune response to *Candida* and are influenced by the site of infection. A detailed discussion of the host immune response to *Candida* is beyond the scope of this chapter, but several excellent reviews are available for more in-depth coverage.[66,108,321]

The initial host response to infection with *Candida* involves recognition of pathogen- associated molecular patterns (PAMPs) present on the fungal cell wall.[321] Pattern recognition receptors (PRRs) on the surface of innate immune cells perform this function, and several classes of PRRs have been identified in the induction of innate host responses to *Candida*, including the Toll-like receptors (TLRs), the C-type lectin receptors (CLRs), and the NOD-like receptors (NLRs).[108] Recognition of yeast and hyphae morphologies is differential, with each form being recognized by different host receptors.[69,322] TLR2, TLR4, and TLR9 have all been implicated as having a key role in recognition of *Candida* and induction of proinflammatory cytokines.[321] CLRs are a large family of receptors with a shared ability to recognize microbial polysaccharides and are thought to be the most important PRR family in the recognition of fungi.[108] Within this family, dectin 1, dectin 2, macrophage mannose receptor 1, dendritic cell-specific ICAM3–grabbing non-integrin (DC-SIGN), and soluble mannose-binding lectin serve to recognize *C. albicans* and are involved in phagocytosis, production of inflammatory cytokines, neutrophil recruitment and activation, and complement activation.[108,322] Finally, NLRs located within the cytoplasm function to activate inflammasomes (protein platforms that induce the activation of interleukin [IL]-1β and IL-18 through caspase 1) and may have an important role in both T-helper cell (Th) type 1 responses and Th17-type responses against *C. albicans*, which are important for containing disseminated and mucosal infection, respectively.[320,328]

Beyond the role of PRRs in the innate immune response to *Candida*, neutrophils, macrophages, and monocytes are all critically important antifungal effector cells, as evidenced by the high risk for disseminated disease in neutropenic patients.[52,76,136,346] Phagocytes already residing in infected organs are involved in the killing of invading *Candida*, whereas neutrophils and monocytes are recruited to the site of infection. The large size of hyphae may preclude engulfment of *Candida* by these phagocytes; however, recent studies have demonstrated the important role of neutrophil extracellular traps (NETs) in the killing of both hyphal and yeast forms.[318,319]

The adaptive immune system plays a critical role in protecting against oropharyngeal candidiasis. Until recently, protective adaptive responses were thought to be mediated by $CD4^+$ Th1 effector cells. However, with the discovery in 2005 of a subset of $CD4^+$ Th17 cells,[115,173,226] it was discovered that Th17-type responses play a crucial role in controlling *C. albicans* at the mucosa.[66,108] This finding is supported by the observation that patients with chronic mucocutaneous candidiasis (CMC)—either as isolated autosomal-dominant CMC (AD-CMC) or as part of a primary immunodeficiency due to hyper-IgE syndrome or autoimmune polyendocrinopathy with candidiasis and ectodermal dystrophy (APECED)—share a common defect related to an inadequate Th17 response. The major genetic defect causing hyper-IgE syndrome is a mutation in the gene encoding STAT3 transcription factor, resulting in impaired Th17 differentiation.[66] Most patients with AD-CMC have a defect in the *STAT1* gene, which is involved in the IL-23/IL-23R pathway crucial for induction of Th17 responses. The mechanism of susceptibility to *Candida* infection in patients with APECED has only recently been elucidated, with the discovery of neutralizing autoantibodies against Th17-type cytokines in affected patients.[158,244]

With respect to hematogenously disseminated candidiasis, the portal of entry of *Candida* into the host bloodstream has been the source of much debate, with both the gastrointestinal tract and the skin being proposed as the source of acquisition. In a remarkable experiment performed in 1969, an investigator ingested 10^{12} *C. albicans* cells and underwent serial blood and urine sampling. After experiencing a transient febrile reaction with chills, *C. albicans* was isolated from the blood and urine within 3 hours of ingestion, forming the only experimental human evidence that persorption through the gut

is the source of candidemia.[168] Animal models of candidal gut colonization and subsequent development of disseminated candidiasis after immunosuppression also support the hypothesis of an intestinal source for candidemia.[211,269,317] In a systematic review of the literature investigating skin or intestinal colonization as the source of candidemia, the authors identified more compelling data in support of intestinal colonization as the primary source.[217] This conclusion is consistent with findings of anaerobic spectrum antibiotics as a significant risk factor for candidemia,[348] because antibiotics with anaerobic activity have been shown to permit a higher and more sustained increase in intestinal colonization with yeasts.[267] However, other portals of entry besides the intestine are important for the development of invasive candidiasis, as evidenced by the increased incidence of candidemia in burn patients[229] and through intravascular devices.[162]

CLINICAL MANIFESTATIONS

Infections due to *Candida* spp. have myriad presentations and depend largely on the immune status of the host as well as the existence of predisposing risk factors. The clinical manifestations of candidiasis in the neonatal population are unique and are discussed separately. Owing to the differences in pathogenesis of candidal diseases, the following section is subdivided into discussions of superficial (mucocutaneous) and invasive disease manifestations.

Superficial Candidiasis

Oropharyngeal Candidiasis

Oropharyngeal candidiasis is one of the most common manifestations of *Candida* infection. Pediatric populations in which oropharyngeal candidiasis can be seen most frequently include young infants, as well as patients with human immunodeficiency virus (HIV) infection, malignancy, or other causes of immunodeficiency, although occurrence in healthy children with other risk factors (e.g., inhaled corticosteroid exposure,[98] broad-spectrum antibiotic exposure[291]) is not uncommon.

The most common manifestation of oropharyngeal candidiasis in children is pseudomembranous candidiasis, or thrush. Pseudomembranous candidiasis is characterized by the presence of white to creamy-colored plaques on the buccal mucosa, tongue, and gums, although less frequently the soft palate, uvula, and tonsils also may be involved. These lesions may be associated with pain and dysphagia, although frequently are asymptomatic.[323] The adherent plaques may be removed by gentle scraping, revealing an erythematous base. Histologic examination of these membranes reveals epithelial cells together with yeast and filamentous forms of *Candida*.[339] Aside from pseudomembranous candidiasis, other forms include erythematous atrophic candidiasis and angular cheilitis. Erythematous atrophic candidiasis most frequently presents as painful erythematous lesions on the dorsum of the tongue and palate, although the buccal mucosa may also be involved. This form is commonly associated with prior broad-spectrum antibiotic exposure and may spontaneously resolve once antibiotics are discontinued and normal bacterial flora restored.[339] Angular cheilitis may appear alone or in conjunction with pseudomembranous or erythematous atrophic candidiasis and is characterized by painful erythema and fissuring at the angles of the mouth. *C. albicans* is the most common species isolated in children with oropharyngeal candidiasis, although *C. tropicalis*, *C. parapsilosis*, and *C. glabrata* also may be found.[100,132,199,221]

Esophageal Candidiasis

Esophageal candidiasis is most commonly seen in severely immunocompromised children and is an acquired immunodeficiency syndrome (AIDS)-defining illness in children infected with HIV. Similar to oropharyngeal candidiasis, other risk factors include immunosuppression due to malignancy, transplantation, or primary immunodeficiency, in addition to corticosteroid exposure (inhaled or systemic) and use of broad-spectrum antibiotics.* Although frequently accompanied by oropharyngeal candidiasis, the absence of oral involvement does not exclude *Candida* esophagitis. In a case series of HIV-infected children receiving highly active antiretroviral therapy, 28 percent of *Candida* esophagitis episodes were not associated with concomitant oropharyngeal candidiasis.[56] Common presenting symptoms include odynophagia, retrosternal/epigastric pain, and dysphagia, although in severely immunocompromised children fever may occasionally occur.[55,56,323]

Findings on endoscopic examination include the presence of white plaques, erythema, and edema of the esophageal mucosa, ulceration, and, in severe cases, strictures. *Candida* spp. may be cultured from endoscopic brushings, although positive isolation does not distinguish from commensal *Candida* colonization. Reliable diagnosis may be made by histologic evidence of tissue invasion in biopsy material.[323] In addition to esophageal endoscopy, barium contrast studies of the esophagus may reveal findings of shaggy mucosal irregularities and nodular filling defects suggestive of esophageal candidiasis, although other radiographic patterns can be seen.[106,176,177]

Vulvovaginal Candidiasis

Vulvovaginal candidiasis is extremely rare before menarche but increases in frequency during late adolescence and adulthood. Between 50 and 70 percent of women may be diagnosed with this condition during their lifetime.[92,290] Risk factors for the development of vulvovaginal candidiasis include diabetes mellitus, pregnancy, oral contraceptives, and use of broad-spectrum antibiotics.[2,289] Unlike other mucosal sites of *Candida* infection, HIV seropositivity is not a clear risk factor for vulvovaginal candidiasis, although rates of *Candida* vaginal colonization have been shown to be significantly higher in HIV-seropositive versus HIV-seronegative at-risk women.[2,275]

*References 13, 16, 112, 137, 160, 276.

Common symptoms include vaginal pruritus, erythema, dysuria, and an odorless, thick, white, curdlike discharge.[7] The diagnosis can be clinically supported by identification of yeast and pseudohyphae/hyphae seen with potassium hydroxide or saline on microscopy, although the sensitivity of microscopy varies between 38 and 83 percent.[7] Isolation of *Candida* from culture of vaginal secretions does not differentiate infection from colonization.

Cutaneous Candidiasis

Cutaneous candidiasis occurs in moist, occluded cutaneous sites that promote maceration of the skin and superficial invasion by *Candida*. Diaper dermatitis is a common manifestation that typically occurs in infants, with peak prevalence during the second to fourth months of life.[124] The lesions of *Candida* diaper dermatitis generally erupt in the perianal area, spreading to involve the perineum and inguinal folds, with confluent erosions, satellite pustules on an erythematous base, and marginal scaling. In infants with darker skin pigmentation, lesions may show hypopigmentation. Evidence of *Candida* colonization in the stool is present in up to 90 percent of children,[251] suggesting that the gastrointestinal tract is the most important source for *Candida* diaper dermatitis. Oropharyngeal candidiasis may be accompanied by diaper dermatitis in 34 to 52 percent of patients, indicating that diaper dermatitis may be the result of successive oral and gastrointestinal colonization.[124] Cutaneous candidiasis may also manifest as intertrigo, occurring in the inframammary, axillary, inguinal, perineal, intergluteal, and interdigital regions. Lesions may appear as pustules on an erythematous base with central confluence, as satellite lesions, and with associated pruritus and tenderness.[342] Folliculitis and balanitis are less common presentations of cutaneous infection.

Chronic Mucocutaneous Candidiasis

Chronic mucocutaneous candidiasis is a clinical syndrome characterized by persistent and/or recurrent *Candida* infections of the oropharynx, skin, nails, and, uncommonly, esophageal candidiasis and laryngitis.[157,161] In some patients, chronic localized *Candida* granulomas may occur, presenting as thick, adherent, hyperkeratotic "warty" lesions on the scalp and face.[157,342] Rather than a single entity, CMC is a manifestation of a number of heterogeneous disorders unified largely by a common downstream defect in mucosal *C. albicans*–induced Th17-type response,[108] although some exceptions exist. CMC can present as an isolated disease (autosomal-dominant chronic disseminated candidiasis [CDC]), or as part of a primary immunodeficiency disorder such as hyper-IgE syndrome, APECED, severe combined immunodeficiency (SCID), DOCK8 deficiency, and deficiencies of IL-12, IL-17, and IL-23.[326] CMC typically presents in infancy or early childhood and may be associated with recalcitrant or relapsing candidal disease despite antifungal therapy. Despite extensive cutaneous and mucosal involvement, reports in the literature of invasive *Candida* infections are rare.

Invasive Candidiasis

Candidemia

The clinical manifestations of candidemia may vary from nonspecific signs of fever and malaise to septic shock and multiple organ dysfunction syndrome.[163] Additional manifestations may be apparent as a result of dissemination through the bloodstream to distal sites such as the central nervous system, the lungs, and kidneys, with the risk for dissemination increasing with the number of days of blood culture positivity and immunosuppression.[1,346] As previously mentioned, prolonged exposure to antibiotics, placement of a central venous catheter or arterial lines, malignancy, mechanical ventilation, and hyperalimentation have all been cited as risk factors for candidemia.[89,184,348]

Acute Disseminated Candidiasis

Endovascular Candidiasis. Endovascular candidiasis presents most commonly as infective endocarditis, although septic thrombophlebitis and mycotic aneurysm are less frequently seen.[202,268] Although data are limited, the frequency of *Candida* endocarditis appears to be increasing over the past 2 decades,[258,306] mirroring the increasing incidence of candidemia reported in the literature. *Candida* may be the most common cause of health care–associated infective endocarditis in children, with one single center study reporting isolation of *Candida* spp. from 27 percent of children with nosocomial infective endocarditis.[191] Clinical manifestations are similar to those of non-*Candida* endocarditis and may include fever, onset of a new or changing murmur on auscultation, hepatosplenomegaly, and congestive heart failure in addition to the embolic and immunologic phenomenon seen with infective endocarditis. Transthoracic or transesophageal echocardiography may reveal the presence of intracardiac thrombus or valvular vegetations.

Risk factors cited for *Candida* endocarditis include prematurity, congenital or acquired heart defects or endovascular prostheses, presence of a central venous catheter, immunosuppression, broad-spectrum antibiotic exposure, and hyperalimentation.[202,306] In a literature review of pediatric *Candida* endocarditis, the frequency of involvement of right-sided intracardiac structures (e.g., right atrium, tricuspid valve) was three times that of left-sided structures for patients in whom the site of intracardiac lesion was reported,[202] likely reflecting the contributory role of central venous catheters as both a source of endothelial trauma and a hematogenous portal of entry of *Candida* in the development of this complication.

Cardiac Candidiasis. *Candida* spp. may be a rare cause of pericarditis and myocarditis in children.[331] At least six cases of pediatric *Candida* pericarditis and five cases of *Candida* myocarditis have been reported in the English literature.[70,274,331] *Candida* pericarditis and myocarditis may occur in the setting of recent cardiothoracic surgery, contiguous focus of pleural or mediastinal infection, contiguous intracardiac spread of infection (e.g., *Candida*

endocarditis), or acute hematogenous dissemination.[274,331] Clinical symptoms of *Candida* pericarditis may be subtle but include fever, chest pain, and dyspnea, with evidence of pericardial rub and cardiac tamponade on examination, enlarged cardiac silhouette on chest radiography, and ST-T wave changes on electrocardiography. Blood cultures may not be positive, complicating early recognition.[70,331] Echocardiography will reveal the presence of a pericardial effusion. Candidal invasion and necrosis of the myocardium may be extensive and produce associated signs of congestive heart failure, with electrocardiographic changes suggestive of myocarditis.[331] Mortality rates in the literature have been high, with only 1 of 11 pediatric patients reported with *Candida* pericarditis and myocarditis having survived, although this may have been due to delayed recognition, because diagnosis was made post mortem in the majority of these cases.[70,274,331]

Pulmonary Candidiasis. Three different patterns of invasive pulmonary candidiasis have been described: primary *Candida* bronchopneumonia due to tracheobronchial colonization and aspiration, secondary pneumonia in the setting of disseminated candidiasis, and secondary pneumonia in the setting of septic emboli.[114,141,227] Primary *Candida* bronchopneumonia is rare, is limited largely to neutropenic patients and neonates, and is thought to occur via aspiration of *Candida* into the upper respiratory tract. In autopsy studies of adults with invasive pulmonary disease with no other sites of dissemination or premortem candidemia, a distinct pattern of intra-alveolar hemorrhage, alveolar exudates, necrosis, and microabscesses with evidence of *Candida* may be present, with several cases also showing evidence of esophageal candidiasis.[114] A similar pattern was seen in autopsies of three infants with evidence of airspace invasive candidiasis concurrent with colonization of the upper respiratory tract and oropharynx.[141]

More commonly, invasive pulmonary candidiasis occurs as a consequence of hematogenous dissemination in a patient with candidemia or from showering of septic thrombi from an infected central venous catheter, septic thrombophlebitis, or *Candida* endocarditis. In disseminated candidiasis, pulmonary involvement is typically capillary invasive, with bilateral lung involvement. On microscopic examination, pseudohyphae are seen to invade the pulmonary capillaries, arterioles, and small arteries, thus entering the lung parenchyma. Microabscesses may be present in the lungs as well as other end-organ sites of dissemination. In embolic pulmonary candidiasis the lungs are seeded with infected emboli from an endovascular source, resulting in hemorrhagic infarcts in the periphery of the lungs and septic thrombi in the small- and medium-sized pulmonary arteries. Extrapulmonary thrombi may also be seen in other sites.[141]

The frequency of *Candida* colonization in the oropharynx and gastrointestinal tract, in addition to the frequent occurrence of tracheobronchial colonization in intubated patients in the intensive care unit, makes the use of bronchoalveolar lavage to distinguish colonization from invasive pulmonary candidiasis untenable. Histologic demonstration of invasion of *Candida* within lung tissue is the only widely accepted criterion for the definitive diagnosis of primary *Candida* pneumonia.[227] In contrast, secondary invasive pulmonary candidiasis may be suspected in the setting of candidemia and/or other sites of disseminated disease. The radiographic pattern of primary *Candida* pneumonia has been described as patchy bilateral consolidation with air bronchograms and rarely localized to one segment. In cases of disseminated candidiasis with secondary pulmonary involvement, multiple 3- to 30-mm nodules containing central necrosis with pseudohyphae and budding yeast may be seen through the lung, with consolidation found in advanced disease. Cavitation is not typically seen.[47,141,227]

Candidiasis of the Peritoneum, Gastrointestinal Tract, and Gallbladder. The most common cause of *Candida* peritonitis is peritoneal dialysis (PD)–associated peritonitis; other causes include perforation of an intra-abdominal viscus or surgery-related peritonitis due to an anastomotic leak. Fungal peritonitis has been reported to occur in 3 percent of all peritonitis episodes in children receiving PD, with *Candida* spp. comprising the vast majority of fungal peritonitis.[205,246,333] Similar to other *Candida* health care device–associated infections, colonization with subsequent biofilm formation of the PD catheter is the presumed mechanism of infection. Common presenting signs and symptoms include fever and abdominal pain; sepsis with hemodynamic instability may also be seen, although extraperitoneal dissemination is rare. An elevated leukocyte count greater than 100/mm^3 in the dialysate may be seen, whereas Gram stain may reveal budding yeast forms. Culture of the dialysate will allow identification of the organism. Recent administration of systemic antibiotics has been consistently noted to be a risk factor for the development of PD-associated fungal peritonitis.[246,333] Outcomes are generally good, with a low mortality rate in children of 0 to 6 percent compared with the 13 to 53 percent mortality seen in adults. In addition, 50 to 70 percent are able to continue PD after treatment for fungal peritonitis.[246,333]

Invasive candidiasis of the lower gastrointestinal tract is an uncommon but well-described entity in severely immunocompromised patients, although the literature has been limited to the adult population.[59,200,242,304] Clinical manifestations include invasive candidal enterocolitis with or without pneumatosis and infarction. Patients may have fever, acute abdominal pain, distention, emesis, and bloody diarrhea. Grossly, hemorrhagic ulcerations and nodules may be seen, occasionally with transmural infarction. White plaques may be seen and mistaken for pseudomembranous colitis. On histopathology, periodic acid–Schiff and Gomori methenamine silver stains may reveal budding yeast and filamentous forms invading the mucosa and submucosa.

In addition to primary and secondary *Candida* peritonitis and invasive intestinal candidiasis, *Candida* has also been described to cause acalculous candidal cholecystitis, as well as biliary obstruction due to *Candida* mycetoma.[48,200]

Candidiasis of the Urinary Tract. The presence of asymptomatic candiduria in children is common,

occurring in 8 percent of healthy males and 12 percent of healthy females. The prevalence increases with exposure to antibiotic therapy, with rates of isolation of up to 39 percent of specimens.[107] In the majority of asymptomatic individuals, the presence of yeast in the urine indicates contamination or colonization. In patients with candidemia, isolation of *Candida* in the urine may signify antegrade infection from hematogenous seeding of yeast to the renal parenchyma, with subsequent development of renal abscesses, renal mycetomas (fungus balls), collecting system obstruction, and renal failure. The clinical significance of candiduria in the setting of an indwelling urinary catheter is less clear, because *Candida* in the urine may signify a catheter-associated urinary tract infection (UTI) or simply colonization and biofilm formation of the catheter in the absence of true infection. Clinical manifestations of *Candida* UTIs may be indistinguishable from those of bacterial UTIs, with dysuria, frequency, urgency, and, in the setting of pyelonephritis, fever and flank pain. In patients with indwelling catheters, symptoms may be less recognizable, either due to a lack of dysuria or due to sedation status impeding the patient's ability to communicate symptoms in the intensive care unit, although suprapubic discomfort may be reported.[142]

In contrast to bacterial UTIs, quantification of *Candida* in the urine does not reliably predict the presence of UTI, based on pediatric and adult studies.[58,142] Although the mean colony counts of children with asymptomatic candiduria may exceed 10^3 colony-forming units (CFU)/mL,[107] biopsy-proven renal infection has been found with colony counts as low as 10^4 CFU/mL in patients without indwelling catheters, whereas in patients with indwelling catheters there may be no correlation between colony count and biopsy-proven renal infection.[142] Although pyuria may be a helpful discriminator of *Candida* UTI in noncatheterized patients, it may also be present in patients with indwelling catheters in the absence of infection.

Given the frequency of perineal *Candida* colonization, asymptomatic patients with *Candida* isolated from the urine should have a repeat midstream clean-catch urine sample sent to verify candiduria. In patients with indwelling catheters, a repeat urine specimen from a newly placed catheter will help to distinguish candiduria from colonization of the catheter. Urinalysis should be performed, because the presence of pyuria, hematuria, and/or leukocyte esterase may be useful in a noncatheterized patient. In patients who are symptomatic, imaging with renal ultrasonography is the preferred modality for identifying renal parenchymal abnormalities as well as obstruction, because it may be more sensitive for the detection of renal mycetomas than other imaging techniques.[250] Renal mycetomas may appear as hyperechoic, nonshadowing foci, whereas renal abscesses may appear as hypoechoic masses.[45,250] Other imaging modalities to identify pyelonephritis, renal abscesses, and renal mycetomas may include computed tomography (CT), magnetic resonance imaging (MRI), and renal cortical scintigraphy.

Osteoarticular Candidiasis. The frequency of *Candida* osteomyelitis appears to be increasing over the past 4 decades, commensurate with the increase in invasive candidiasis as described earlier.[99] Risk factors cited include presence of a central venous catheter, history of preceding candidemia, prior surgery, use of broad-spectrum antibiotics, and immunosuppression.[99,284] The most common sites of involvement in children (in descending order) are the femur and humerus, with ribs, vertebra, and sternum being much more infrequent. In a review of 207 cases of *Candida* osteomyelitis in children and adults, children were significantly more likely to have femur (OR, 20.5; 95% CI, 8.4 to 48.1) or humerus (OR, 46.3; 95% CI, 12.9 to 169) involvement and significantly less likely to have vertebral involvement (OR, 0.09; 95% CI, 0.04 to 0.25). Involvement of more than one site is common, with 84 percent of cases having two or more bones infected.[99] The clinical presentation of *Candida* osteomyelitis is indolent, with 90 percent reporting local pain, tenderness, erythema, and swelling lasting several weeks to months. Fever may be present in a minority of cases. Draining sinus tracts are more likely to occur with nonvertebral osteomyelitis (32%). An elevated erythrocyte sedimentation rate and C-reactive protein level are commonly seen. Imaging with radionuclide scanning may reveal multiple sites of involvement; MRI may reveal bone destruction, soft tissue extension, and abscess formation, with decreased signal intensity on T1-weighted imaging and increased signal intensity on T2-weighted imaging.[99] In the absence of candidemia, biopsy of the involved site(s) with culture and histopathology stains may be necessary to secure the diagnosis.

Up to 85 percent of cases of pediatric fungal arthritis occur in infants younger than 6 months of age.[302] Arthritis concomitant with bone involvement has been reported to occur in 11 to 80 percent of cases, with the most common synovial joints infected being the knee (11%) and hip (5%).[82,99,302] Infection originates hematogenously, with seeding of the synovium and/or metaphyseal vessels resulting in septic arthritis and osteomyelitis, respectively. *Candida* septic arthritis has been reported to manifest several months to a year after the initial episode of candidemia.[116,302] Although two thirds of patients may have acute symptoms of fever and painful swelling of the joint, *Candida* arthritis may also present indolently. Arthrocentesis of the affected joint may reveal leukocyte counts of 7,500 to 151,000/mm^3 with a neutrophilic predominance; *Candida* may be isolated from cultures of the synovial fluid. Histopathologic examination of the synovium may reveal a nonspecific mononuclear inflammatory infiltrate with thickening of the synovium. In contrast to other fungal arthritides, granuloma formation is uncommon with *Candida* arthritis.[82,302]

Central Nervous System Candidiasis. *Candida* infection of the central nervous system (CNS) can involve any part of the brain or spinal cord, manifesting as acute or chronic meningitis, ventriculitis, microabscesses, or macroabscesses. CNS involvement is most commonly a complication of hematogenous spread, occurring in 12 percent of children with candidemia. Up to 66 percent of patients with *Candida* infection of the CNS will have had a recent or concurrent positive blood culture at the

time of diagnosis.[113,197,346] Involvement of the CNS through direct inoculation at the time of surgery or through infection of an intracranial device (e.g., ventriculoperitoneal shunt, external ventricular drain) may also occur. Outside the neonatal period, patient populations most at risk for *Candida* CNS infection include patients with hematologic malignancy, hematopoietic transplant patients, and neurosurgical patients.[103,113,197]

The clinical manifestations of CNS candidiasis vary depending on the patient population and the type of involvement. Profound immunosuppression with neutropenia and consequent limited ability to mount an inflammatory response may lead to subtle symptoms in oncologic and transplant patients with candidal meningitis and brain abscesses. In a single-center case series of 12 children with leukemia who were diagnosed with candidal meningitis, 42 percent were asymptomatic with the exception of fever, which occurred in all of the patients.[197] Only 50 percent exhibited an altered level of consciousness, whereas other symptoms included seizures (33%), nuchal rigidity (25%), headache (25%), and cranial nerve abnormalities (17%). Similarly, in a case series of 19 pediatric and adult bone marrow transplant patients with *Candida* brain abscesses, 84 percent of patients had fever; other less frequent signs and symptoms included altered mental status (42%), cranial nerve abnormalities (26%), seizures (16%), and hemiplegia (11%). Headache, papilledema, nausea, and vomiting were uncommon, and nearly one third had no signs or symptoms, with diagnosis being made post mortem.[113] In both studies, findings of cerebrospinal fluid (CSF) analysis were often unremarkable, with at least half of subjects in each series lacking pleocytosis, with mildly elevated protein levels and hypoglycorrhachia in only a minority of patients. In those with CSF pleocytosis, a neutrophilic predominance is typically seen,[10,65,113,183] although a mononuclear predominance may be seen in neutropenic patients.[197] MRI appears to be more sensitive than CT in the detection of brain abscesses; however, 60 percent of patients with *Candida* brain abscesses may have normal scans, likely related to the difficulty in detecting microabscesses on imaging. *Candida* frequently produces multiple brain abscesses, with half of affected patients having three or more lesions based on autopsy evaluation.[113] Dissemination of *Candida* to other organs is frequently seen in addition to intracranial infection. Outcomes of CNS candidiasis are poor, with an associated 30 to 100 percent mortality.[103,113,131,197]

In patients with intracranial devices, isolation of *Candida* from the CSF may represent colonization of the device or true intracranial infection. In a case series of 21 neurosurgical patients from whom *Candida* was isolated from CSF, 9 patients with a single CSF culture did not receive antifungal therapy, with 4 undergoing removal of the intracranial drain as the only intervention.[103] It is worthwhile to mention that these patients also had normal CSF parameters and were clinically asymptomatic. In contrast, 10 patients had multiple positive CSF cultures and were treated for *Candida* meningitis; most were symptomatic, with lethargy, fever, meningismus, focal neurologic signs, and neutrophilic pleocytosis. Isolation of *Candida* as a contaminant may occur even in the absence of an intracranial device. In a single-center case series of 23 infants and children from a single institution with fungi isolated from the CSF, 6 patients—the majority of whom did not have an intracranial device, and of whom 5 had a negative CSF culture on repeat sampling—were considered to have *Candida* as a contaminant and did not receive antifungal therapy, with a good outcome.[10] Both of these studies highlight the importance of repeated CSF cultures as well as presence of clinical symptoms in the interpretation of *Candida* isolated from the CSF.

Ocular Candidiasis. *Candida* may involve the eye during the course of candidemia and subsequent disseminated disease, with involvement reported in up to 8 percent of children with disseminated disease.[346] Endophthalmitis may be initiated by hematogenous seeding of the choroid and retina through the small vessels, with subsequent chorioretinitis manifesting as white chorioretinal lesions, or "fluff balls," on the posterior fundus.[19] Vitritis is marked by extension of inflammation into the vitreous. Hypopyon, scleritis, and optic nerve involvement may also occur. In patients who are able to report symptoms, "floaters" and blurred vision are the most common complaint.[279]

Chronic Disseminated Candidiasis

Chronic disseminated candidiasis, also known as hepatosplenic candidiasis, is a distinct form of invasive candidiasis seen primarily in patients with leukemia and treatment-induced neutropenia. Involvement predominantly occurs in the liver, spleen, and occasionally other organs. *Candida* colonization of the gastrointestinal tract with subsequent dissemination through the portal venous circulation during periods of neutropenia is thought to be the predominant cause of this disease entity. Prolonged neutropenia is the most-cited risk factor for CDC; other reported risk factors include younger age and exposure to quinolone prophylaxis.[193,266] CDC most commonly presents in the course of neutrophil recovery and thus is thought to represent a form of immune reconstitution syndrome against invasive fungal infection. Symptoms of CDC include persistent fever (85%) and right upper quadrant pain (57%).[303] The most common laboratory finding is a persistent and significantly elevated serum alkaline phosphatase level (median duration 130 days); serum bilirubin and transaminase levels may exhibit brief elevation.[303] Blood cultures may be positive in less than 20 percent of patients with CDC, necessitating the need for biopsy and identification of *Candida* elements on histopathology or culture to confirm the diagnosis. CT has been shown to be more sensitive than ultrasonography for the detection of hepatosplenic lesions, although MRI may be superior to both imaging modalities.[193,277] Lesions are typically not apparent until neutrophil recovery and manifest as "wheel in wheel" target lesions composed of a central necrotic focus of yeast and filamentous forms with a surrounding rim of intense inflammatory infiltrate.[303] Serial imaging with CT or ultrasound is necessary to follow the resolution of lesions on antifungal therapy; lesions may decrease in size or disappear during

subsequent periods of neutropenia, underscoring the importance of follow-up imaging during neutrophil recovery.[231]

DIAGNOSIS

Culture

Isolation of *Candida* spp. from cultures of blood or other sterile sites is the gold standard of laboratory-based microbiologic confirmation of invasive candidiasis. Microbiologic confirmation is often challenging, however, owing to the low sensitivity of blood cultures in patients with invasive candidiasis, with rates of isolation ranging from 0 to 43 percent.[34,223,303] One study demonstrated that even when aerobic blood culture bottles were deliberately spiked with 10^3 *Candida* yeast cells, the yield was only 90 percent.[128]

Based on studies evaluating the yield of blood culture systems inoculated with *Candida*, the sensitivity of commercially available blood culture media to detect candidemia varies by the type of culture medium (aerobic, anaerobic, mycologic), inoculum size, and blood culture system. Depending on the blood culture system used, mycologic blood culture bottles may provide a slight advantage in the recovery of *Candida* owing to the added benefit of a lysing agent to release viable phagocytosed fungal cells, the addition of nutrients essential to fungal growth, as well as antibiotics to suppress competitive bacterial growth in case of coinfection.[127] Time to positivity is dependent on inoculum size as well as specific *Candida* spp.[104] With the use of current automated blood culture systems, most *Candida* spp. have growth detected within 24 to 36 hours, even at densities of 1 colony-forming unit/mL, although *C. glabrata* has been shown to exhibit significantly longer time to positivity.[104,127]

Although *Candida* spp. can grow on routine sheep's blood agar, use of a selective fungal medium such as Sabouraud dextrose agar or chromogenic *Candida* agar may enhance isolation of organisms from other types of body fluid and tissue specimens. However, despite the presence of visible yeast and pseudohyphae in the specimen, tissue cultures may still be negative, as evidenced by a study of 45 oncologic patients with hepatosplenic candidiasis who underwent biopsy, with negative cultures in 56.5 percent.[303] Prior antifungal exposure, nonviable organisms in the specimen, and sampling error may contribute to negative culture results.

Histology

Histopathologic examination of tissue specimens may be an important alternative means to diagnose invasive candidiasis in suspected cases when cultures are negative and may be important in differentiating tissue invasion from surface colonization. Yeast, hyphae, and pseudohyphae may be visible on hematoxylin and eosin stain. Special fungal stains such as Gomori methenamine silver and periodic acid–Schiff should be utilized to enhance identification of *Candida* structures.

Antigen

In light of the poor sensitivity of blood cultures in patients with invasive candidiasis, alternative means of establishing a rapid diagnosis have been pursued. Most promising is the use of the serum marker (1→3)-β-D-glucan (BDG), a major cell wall component of most fungi (except *Mucorales* and *Cryptococcus* spp.). BDG is released into the blood and tissues during invasive fungal infection, allowing the use of BDG antigen-based assays for the indirect diagnosis of invasive candidiasis. Commercially available BDG assays such as Fungitell, Fungitec, Wako turbidimetric assay, and Maruha colorimetric assay harness the ability of BDG to activate a coagulation cascade in amebocyte lysate from the horseshoe crab in what is called the limulus test, allowing measurement of this reaction through colorimetric or turbidimetric methods.[138] A meta-analysis of 23 cohort and case-control studies examined the performance of various BDG assays in predominantly adult populations with heterogeneous characteristics, with a pooled sensitivity of 76.8 percent and pooled specificity of 85.3 percent for proven or probable invasive fungal infection.[138] Study definitions for proven or probable invasive fungal infection were based on the 2008 revised European Organization for Research and Treatment of Cancer/Invasive Fungal Infections Cooperative Group and the National Institute of Allergy and Infectious Diseases Mycoses Study Group (EORTC/MSG) definitions of invasive fungal disease.[72] Another meta-analysis of six cohort studies of the performance of the BDG assay in adults with hematologic malignancies found a lower pooled sensitivity of 49.6 percent but higher specificity of 98.9 percent using two consecutive results as criteria for a positive result.[172] Because of the discriminatory power of this assay, BDG assays have been incorporated into the EORTC/MSG definition of probable invasive fungal disease as indirect evidence meeting mycologic criteria.[72]

In contrast to the adult population, data on the use of BDG assays in children have been limited. Mean serum BDG levels in healthy children have been found to be higher than that in adults (68 pg/mL vs. 48 pg/mL, respectively), with lower specificities at preestablished cutoffs of 60 pg/mL and 80 pg/mL than that reported in the literature for adults.[285] In addition, a prospective study evaluating *Candida* colonization and BDG serum values in children with leukemia demonstrated that 30 percent of colonized children exceeded the assay manufacturer positive cutoff values. None of the children developed evidence of invasive fungal infection, and the authors postulated that absorption of BDG through the gut or other sources of false-positive findings may have contributed to this result.[204] Prospective studies are needed to validate the clinical utility of this test in the pediatric population.

In addition to BDG assays, the use of mannan antigen assays to diagnose invasive candidiasis has been examined. Mannan is an immunogenic polysaccharide that comprises a major component of the cell wall in *Candida* spp. and can be found in serum during infection. Different assays have been developed to detect mannan antigen or anti-mannan antibodies, with enzyme-linked

immunosorbent assays (ELISAs) being the most frequently used in Europe[201]; however, none has yet been approved for use in the United States. A meta-analysis of 14 studies evaluating the test characteristics of the mannan and anti-mannan antibody assays for proven and probable invasive candidiasis (based on EORTC/MSG criteria) demonstrated a pooled sensitivity of 58 percent and specificity of 93 percent for mannan antigen. The anti-mannan antibody assay had a pooled sensitivity of 59 percent and specificity of 83 percent, whereas the pooled sensitivity of using combined mannan antigen and anti-mannan antibody assays was 83 percent, with a specificity of 86 percent.[201] Significant heterogeneity of the studies in the meta-analysis was detected, however, and data have been extremely limited in the pediatric population. False-positive results for both mannan antigen and anti-mannan antibody in patients with *Candida* colonization have also been reported, limiting the utility of these assays.[230,278]

Molecular-Based Testing

Polymerase chain reaction (PCR)–based assays show immense potential for improving our capability for early diagnosis of invasive *Candida* infections. The ribosomal RNA gene cluster contains the 18 Svedburg (S), internal transcribed spacer (ITS) 1 and 2, 5.8S, and 28S regions and is a popular amplification target.[166] The presence of multiple copies of this ribosomal RNA cluster in fungal cells increases the sensitivity of PCR. Because blood samples for culture may contain only a small number of fungal cells (1 cell/mL),[237] PCR-based assays have a tremendous advantage, being able to detect down to 0.22 cell/mL depending on the platform.[166] In addition, DNA derived from both dead and living *Candida* cells can be amplified. Numerous DNA amplification methods have been developed, including nested PCR, multiplex PCR, and real-time (RT) PCR platforms. Most studies have reported sensitivities near or equal to 100 percent, with specificity greater than 90 percent.[166] Two studies that examined the use of PCR to detect invasive candidiasis exclusively in the pediatric population—one in the neonatal and pediatric intensive care units and the other in an oncologic population with fever and neutropenia—also demonstrated high sensitivity, although no explicit control group was included.[73,305] In a prospective study comparing *Candida* RT-PCR, BDG assay, and blood cultures in the diagnosis of invasive candidiasis in 73 hospitalized adults, RT-PCR outperformed BDG for the detection of deep-seated candidiasis (89% vs. 53%, p = .004).[214] PCR-based assays for the detection of *Candida* are a promising test modality, and further prospective validation studies as well as standardization of PCR techniques are needed to determine whether they can be incorporated into clinical practice.

ANTIFUNGAL PROPHYLAXIS

Consideration for antifungal prophylaxis has been given primarily to patients with the greatest risk factors for invasive fungal infection. Data from clinical trials on the efficacy of antifungal prophylaxis in the oncologic, liver transplant, intensive care unit, and surgical populations derive largely from studies in adults; antifungal prophylaxis in the neonatal population is a notable exception and is discussed later in the section on neonatal candidiasis.

Children undergoing chemotherapy for hematologic malignancies are at significantly high risk for developing invasive fungal infections, of which *Candida* spp. is most commonly identified. High-risk categories in this group can be refined further, with acute myeloid leukemia, relapsed acute lymphoblastic leukemia, allogeneic or autologous hematopoietic stem cell transplant, and graft-versus-host disease being associated with rates of invasive fungal infection ranging from 9 to 29 percent.[77] Severe aplastic anemia, although not an oncologic process, is also associated with a significant risk for invasive fungal infection owing to bone marrow failure and prolonged neutropenia.[310] Given the notable frequency of invasive fungal infection and high mortality rates associated with invasive *Candida* infections in these patients,[311] extrapolation from comparative data in adults with regard to the benefits of antifungal prophylaxis is reasonable. In a meta-analysis of 64 randomized, controlled trials of antifungal prophylaxis in cancer patients after chemotherapy or hematopoietic stem cell transplant, antifungal prophylaxis led to a significant decrease in all-cause mortality, fungal-related death, documented invasive *Candida* infection, and occurrence of any invasive fungal infection, compared with placebo, no treatment, or nonsystemically absorbed antifungal agents. The greatest benefit was seen in allogeneic and autologous hematopoietic stem cell transplant patients.[255] A detailed discussion regarding the comparative effectiveness of different antifungal prophylaxis regimens is beyond the scope of this chapter, but with regard to the type of antifungal prophylaxis, fluconazole is currently the most commonly recommended agent in high-risk children, given its proven survival benefit, low adverse effects, and comparatively less common drug interactions compared with alternatives.[77,309] In patients for whom broader antifungal coverage may be indicated, the extended-spectrum triazoles and the echinocandins are alternative options.[77,308,311] Prophylaxis should be given during induction chemotherapy through resolution of neutropenia, during hematopoietic stem cell transplantation until engraftment, and in patients with severe graft-versus-host disease.[224]

Although pediatric liver transplant recipients have been identified as having high rates of invasive candidiasis,[49,105] pediatric studies to elucidate risk factors are limited, as well as prospective studies showing a clinical benefit from antifungal prophylaxis. Based on adult literature, current Infectious Diseases Society of America recommendations are to administer fluconazole 3 to 6 mg/kg daily or liposomal formulation amphotericin B (LFAB) 1 to 2 mg/kg daily as postoperative prophylaxis for 7 to 14 days for liver transplant recipients with at least two of the following risk factors: retransplantation, creatinine level greater than 2.0 mg/dL, choledochojejunostomy, intraoperative use of more than 40 units of blood products, prolonged intraoperative time (>1 hour), and fungal colonization detected at least 2 days prior and 3 days after transplantation.[224] Small bowel transplant recipients also appear to be at high risk for invasive

fungal infection,[91] and expert consensus recommends fluconazole 6 mg/kg/day for at least 2 weeks after transplantation.[224]

The benefit of antifungal prophylaxis in pediatric intensive care unit patients remains unclear, because more data are needed to prospectively identify those patients at highest risk for invasive candidiasis, as well as to define the benefit of targeted antifungal prophylaxis in this population. Based on data from adults, current guidelines suggest that antifungal prophylaxis may be warranted in intensive care units with very high rates of invasive candidiasis and in patients who are at highest risk (>10%) for invasive candidiasis.[224]

TREATMENT

The approach to treatment of superficial and invasive candidiasis should take into consideration the source of infection (e.g., endovascular, medical-device associated), site(s) of involvement, *Candida* spp. and susceptibility profile, prior antifungal exposure, and clinical status of the host, as well as drug-specific factors such as pharmacokinetic and pharmacodynamics properties and potential for drug interactions. This section focuses on the management of superficial and invasive candidiasis in the non-neonatal pediatric population, and relies heavily on updated clinical practice guidelines issued by the Infectious Diseases Society of America.[224] Detailed discussions of individual properties of antifungal agents are discussed in a separate chapter and will not be reviewed here. However, the choice of antifungal therapy for *Candida* infections is influenced largely by the species causing the infection, because certain *Candida* spp. exhibit characteristic antifungal susceptibility profiles. Knowledge of these susceptibility characteristics may help guide empirical therapy while awaiting antifungal susceptibility testing results. Table 199-1 illustrates the general pattern of susceptibility to antifungal agents among *Candida* spp.

Although the susceptibility of *Candida* spp. may generally be predictable, individual isolates may not necessarily follow this pattern. Although routine susceptibility testing is not typically performed for *C. albicans* owing to its low rate of resistance, expert opinion suggests that susceptibility testing should be performed for *C. glabrata* and for other *Candida* spp. when treatment failure has occurred or when azole resistance is suspected.[224] In general, the echinocandins are preferred for infection due to *C. glabrata*, although transition to fluconazole or voriconazole is possible if susceptibility of the isolate is confirmed. Fluconazole is preferred for the treatment of infections due to *C. parapsilosis*. The MIC values for echinocandins tend to be higher for *C. parapsilosis* than for other common *Candida* spp. owing to the presence of an intrinsic *FKS1* mutation encoding glucan synthase.[36] Although some treatment failures in patients with *C. parapsilosis* infections treated with echinocandins have been reported, the clinical significance of higher echinocandin MIC values in this species remains unclear.

Superficial Candidiasis

Oropharyngeal Candidiasis

Most patients with oropharyngeal candidiasis will respond to topical antifungal therapy, although in patients with moderate to severe disease, systemic antifungal therapy may be required. In children with mild cases of oropharyngeal candidiasis, 4 to 6 mL of nystatin suspension (100,000 U/mL) may be administered four times daily in a swish and swallow.[224] Effort should be made to prolong contact time with the oral mucosa as long as possible before swallowing because nystatin does not adhere well to the oral mucosa.[124] Clotrimazole 10-mg troches administered five times daily or one to two nystatin pastilles (200,000 U each) administered four times daily are alternatives.[224] For infants, 100,000 to 200,000 units can be painted onto the affected areas four times daily. When applicable, sterilization of bottle nipples and pacifiers after each use should be attempted to reduce reintroduction of *Candida* through colonized surfaces. Treatment should be administered for 7 to 14 days.

For moderate to severe disease, systemic antifungal therapy is warranted. Oral fluconazole 3 to 6 mg/kg may be administered for 7 to 14 days. For fluconazole-refractory disease, itraconazole solution 2.5 mg/kg twice daily has been shown to be effective and safe in phase 2 clinical trials in children with cancer, liver transplantation,

TABLE 199-1 **General Patterns of Susceptibility of *Candida* Species**

	Species					
Antifungal Agent	***C. albicans***	***C. tropicalis***	***C. parapsilosis***	***C. glabrata***	***C. krusei***	***C. lusitaniae***
Fluconazole	S	S	S	S-DD to R	R	S
Itraconazole	S	S	S	S-DD to R	S-DD to R	S
Voriconazole	S	S	S	S-DD to R	S	S
Posaconazole	S	S	S	S-DD to R	S	S
Flucytosine	S	S	S	S	I to R	S
Amphotericin B	S	S	S	S to I	S to I	S to R
Echinocandins	S	S	S to R*	S	S	S

*Echinocandin resistance among *C. parapsilosis* isolates uncommon.
I, intermediately susceptible; R, resistant; S, susceptible; S-DD, susceptible dose-dependent.
From Pappas PG, Kauffman CA, Andes D, et al. Clinical practice guidelines for the management of candidiasis: 2009 update by the Infectious Diseases Society of America. *Clin Infect Dis* 2009;**48**:503-35.

or HIV infection for the treatment of oropharyngeal candidiasis. Use of itraconazole in children is off label, because it has not been approved for use in children younger than 18 years of age.[110] In children 2 to 11 years of age or 12 to 14 years old and weighing less than 50 kg, voriconazole 9 mg/kg (maximum, 350 mg) orally every 12 hours may be administered, whereas in children 12 to 14 years old and weighing 50 kg or more or older than 14 years should receive 200 mg orally every 12 hours as maintenance dosing.[95,110]

In the event of treatment failure, amphotericin B deoxycholate (AmBd) given as an oral 1-mL suspension four times daily may be tried. Intravenous caspofungin at 70 mg/m^2/day on day 1 followed by 50 mg/m^2/day (maximum, 70 mg) daily on subsequent days may be given in children 3 months of age or older for refractory disease. If chronic suppressive therapy is warranted (e.g., HIV infection or severe immunosuppression), fluconazole may be administered three times weekly.[110,224]

Esophageal Candidiasis

The treatment of esophageal candidiasis requires systemic antifungal therapy. Oral fluconazole at 3 to 6 mg/kg/day for 14 to 21 days is recommended. Intravenous fluconazole at 6 mg/kg/day, AmBd at 0.3 to 0.7 mg/kg/day, or caspofungin 70 mg/m^2/day on day 1 followed by 50 mg/m^2/day (maximum, 70 mg) daily should be used for patients unable to tolerate oral therapy. For fluconazole-refractory disease, itraconazole, voriconazole, or caspofungin are suitable alternatives (see earlier discussion for pediatric dosing). As in oropharyngeal candidiasis, chronic suppressive therapy with fluconazole three times weekly may be administered.[224]

Vulvovaginal Candidiasis

The approach to the treatment of vulvovaginal candidiasis varies depending on the presence of complicated vulvovaginal disease (severe disease is suggested by four episodes of symptomatic vulvovaginal candidiasis in 1 year, non–*C. albicans* infection, or abnormal host). No data have shown the superiority of any topical regimen,[252,288] and a meta-analysis of 19 randomized, controlled trials has shown equivalent results with both oral and topical antifungal agents.[219] Uncomplicated vulvovaginal candidiasis may be treated with a single 150-mg dose of oral fluconazole. Patients with complicated vulvovaginal candidiasis are recommended to undergo induction therapy with a topical or oral azole for 10 to 14 days followed by oral fluconazole 150 mg weekly for 6 months.[224]

Cutaneous Candidiasis

Because moist, macerated skin promotes the development of cutaneous candidiasis, it is important to keep affected areas dry as much as possible; antifungal therapy alone usually does not produce a cure. For candidal diaper dermatitis, frequent diaper changes should be performed. Topical antifungal therapy with nystatin or azoles may be applied three to four times daily.

Invasive Candidiasis

Candidemia

All pediatric patients who are found to be candidemic should be treated with systemic antifungal therapy. For non-neutropenic patients who are critically ill with candidemia or who have had recent azole exposure, an echinocandin is the preferred therapy owing to its significant fungicidal activity against *Candida*. For neutropenic patients who are critically ill due to candidemia or have had recent azole exposure, either an echinocandin or LFAB (3 to 5 mg/kg daily) may be given. Fluconazole therapy may be given as first-line therapy for patients who remain hemodynamically stable and have not had recent azole exposure and should be given intravenously at 6 to 12 mg/kg/day. Step-down therapy from an echinocandin to fluconazole is recommended for patients with susceptible isolates, whereas voriconazole may be offered as step-down oral therapy for candidemia due to *C. krusei* or susceptible *C. glabrata*.[224] In children age 2 to 11 years, or 12 to 14 years and weighing less than 50 kg, voriconazole may be given as a 9 mg/kg IV loading dose every 12 hours on day 1, followed by 8 mg/kg intravenously every 12 hours as maintenance. Oral dosing may be given as 9 mg/kg (maximum, 350 mg) every 12 hours. In children 12 to 14 years of age and weighing 50 kg or more, or older than 14 years, dosing should be as in adults and may be given as a 6-mg/kg intravenous loading dose every 12 hours on day 1, followed by 4 mg/kg IV every 12 hours as maintenance dosing, whereas oral dosing may be given as 200 mg every 12 hours as maintenance dosing.[95,110,224]

A dilated funduscopic examination should be performed in all patients with candidemia within the first week after initiation of antifungal therapy, and routine blood cultures should be performed to document clearance of *Candida* from the bloodstream. In patients without evidence of disseminated disease, antifungal therapy should continue for 14 days from symptom resolution and documented bloodstream clearance of *Candida*. In patients with candidemia in the setting of neutropenia, neutrophil recovery should occur prior to completion of therapy. Current guidelines recommend that central venous catheters in non-neutropenic patients with candidemia should be removed when possible, because data from most observational studies in children and adults have shown fewer rates of complications, reduced mortality, and more rapid rates of response to antifungal therapy.[8,71,228,254] However, concerns of confounding due to the observational nature of these studies, and the possibility that patients whose central venous catheter was retained had significantly higher severity of illness compared with those whose catheters were removed (thus precluding catheter removal), have limited the strength of this recommendation.[218]

In patients who are neutropenic, the gastrointestinal tract may be a more likely source of candidemia; thus, the significance of catheter removal when candidemia is documented is less clear. In a single-center study of 404 patients with cancer and central venous catheters in place at the time of candidemia, the investigators attempted to

differentiate candidemia associated with the central venous catheter versus candidemia associated with a noncatheter source and to define the benefit of timing of catheter removal on resolution of candidemia-associated symptoms and blood culture sterilization. In patients with evidence of catheter-associated candidemia, catheter removal 72 hours or earlier from first positive blood culture was found to be significantly associated with improved response rates compared with removal after 72 hours, whereas patients with candidemia due to an alternate or undefined source did not have a statistically significant improvement in response rates with early catheter removal.[245]

Other data have shown mixed results in support of early removal of catheters in candidemic patients with cancer.[181,324] Based on expert opinion, catheter removal should be attempted for neutropenic patients with persistent candidemia when feasible.[224]

Endovascular Candidiasis

Fungicidal regimens are preferred for *Candida* endocarditis, and most experience in the literature involves the use of AmBd with or without flucytosine for treatment of *Candida* endocarditis. LFAB is associated with less toxicity and permits higher dosages; thus, LFAB 3 to 5 mg/kg with or without flucytosine 25 mg/kg four times daily is recommended for the treatment of native valve and prosthetic valve *Candida* endocarditis in the non-neonatal population. High-dose caspofungin has also been used with some success in the adult population and is considered an alternative.[224]

Based on data from case reports, case series, and a meta-analysis,[85,295] adjunctive surgery plus medical antifungal therapy appears superior to medical therapy alone in reducing the risk for death and forms the basis for recommendations that patients with *Candida* endocarditis should undergo valve replacement, with valve repair and vegetectomy being alternative approaches. Therapy duration for native valve endocarditis is at least 6 weeks from valve replacement, and possibly longer in the presence of perivalvular abscess or other complications. For prosthetic valve endocarditis, suppressive therapy with fluconazole after completion of initial therapy is recommended to prevent late recurrence.

Cardiac Candidiasis

Data are limited to guide management of *Candida* pericarditis,[274] but experience in the literature with AmBd, and the known lower toxicity profile seen with LFAB, suggests that pericarditis can be treated with LFAB at a dose of 3 to 5 mg/kg/day. AmBd at 0.6 to 1 mg/kg/day, high-dose caspofungin, and fluconazole 6 to 12 mg/kg/day are acceptable alternatives. Treatment should be continued for several months, in combination with either a pericardial window or pericardiectomy, because this appears to be the best approach for achieving cure.[224,274] Step-down therapy to fluconazole 6 to 12 mg/kg daily can be considered in patients who are clinically stable and who have shown an initial response to LFAB, AmBd, or caspofungin. Myocarditis should be treated with LFAB or AmBd with or without flucytosine for a minimum of 6 weeks; in the presence of myocardial abscesses, treatment may need to be prolonged.[224]

Peritoneal Candidiasis

Most experts agree that peritoneal catheters should be removed in patients with fungal peritonitis, based on high rates of treatment failure seen in case series of patients with retained catheters, as well as the known challenges involved in treating biofilm present on the device.[50,159,206] Recent recommendations call for prompt (<24 hours) removal of the peritoneal catheter on diagnosis of fungal peritonitis,[178] with recent data showing reduced mortality in adults with early catheter removal compared with delayed removal, although timing of catheter removal continues to be controversial.[51] Medical therapy for fungal peritonitis traditionally utilized intravenous AmBd, although with the discovery that intravenous AmBd has poor peritoneal penetration owing to its high protein binding, oral or intravenous fluconazole with or without flucytosine has been considered the drug of choice for susceptible isolates.[41,194] Fluconazole may also be given intraperitoneally as a 75-mg/L concentration added daily to the dialysate after a systemic loading dose.[205] Intraperitoneal administration of AmBd has been associated with severe peritoneal irritation as well as fibrosis and membrane loss and should be avoided.[9] The role of echinocandins in fungal peritonitis is not yet well defined.

Candidiasis of the Urinary Tract

No treatment is recommended for patients with asymptomatic candiduria. In patients with an indwelling catheter, removal of the device may be adequate to resolve the candiduria without antifungal therapy. In patients with evidence of cystitis, fluconazole is highly water soluble and is primarily excreted into the urine as active drug, and expected urinary concentrations are greater than 10-fold that in serum, exceeding the MIC even for susceptible dose-dependent *Candida* spp.[90] Fluconazole should be given at 3 mg/kg daily for 2 weeks. For fluconazole-resistant organisms, AmBd 0.3 to 0.6 mg/kg/day for 1 to 7 days and oral flucytosine 25 mg/kg dour times daily for 7 to 10 days are alternatives.[224] Continuous bladder irrigation with AmBd has also been used to treat *Candida* cystitis, although relapse rates are high.[90]

For pyelonephritis, higher doses of fluconazole may be needed for adequate tissue penetration and fluconazole 3 to 6 mg/kg daily should be administered for 2 weeks. For fluconazole-resistant strains, AmBd 0.5 to 0.7 mg/kg/day with or without flucytosine 25 mg/kg four times a day should be given.[224] LFAB should not be used to treat *Candida* UTIs because of the low drug levels achieved in the renal parenchyma and urine. Although voriconazole has been shown in an animal model of renal parenchymal candidiasis to be superior to AmBd or fluconazole, urine voriconazole levels are low, with less than 5 percent of the active drug excreted, limiting its utility in the treatment of UTIs. Likewise, the echinocandins have been shown in experimental models to clear renal parenchymal infections in the setting of disseminated

candidiasis, but very little active drug is excreted in the urine and clinical experience with treatment of UTIs is limited.[90]

Patients with mycetomas (fungus balls) in the urinary collecting system are recommended to undergo aggressive surgical débridement to relieve obstruction and to remove the bulk of the mass. Systemic treatment alone is unlikely to result in spontaneous disruption and passage of the mycetoma but should be administered due to the likelihood of coexistent disseminated candidiasis or renal parenchymal infection.[90] Fluconazole 3 to 6 mg/kg/day or AmBd 0.5 to 0.7 mg/kg/day with or without flucytosine is recommended. Irrigation of the renal collecting system with AmBd 50 mg/L in sterile water may be a possible adjunct to systemic therapy. Treatment should continue until urine cultures are negative and symptom resolution has occurred.[224]

Osteoarticular Candidiasis

The management of osteoarticular *Candida* infections is challenging, with high rates of treatment failure associated with relapsed disease despite prolonged antifungal therapy.[99] Fluconazole 6 mg/kg/day for 6 to 12 months or intravenous LFAB at 3 to 5 mg/kg/day for at least 2 weeks followed by step-down therapy to fluconazole at 6 mg/kg/day for 6 to 12 months is currently recommended. Caspofungin may be a suitable alternative to upfront parenteral LFAB administration. Adjunctive surgical débridement may be beneficial in select cases.

For septic arthritis, a minimum of 6 weeks of fluconazole 6 mg/kg/day or LFAB 3 to 6 mg/kg/day for at least 2 weeks followed by fluconazole 6 mg/kg/day is recommended. Adequate surgical drainage is a crucial aspect of the management of non-neonatal *Candida* arthritis and should be performed in all cases.[224]

Central Nervous System Candidiasis

Most experience in the literature regarding the treatment of *Candida* CNS infections has been with AmBd, with or without flucytosine.[10,103] LFAB has been preferred owing to its lower toxicity profile and known tissue penetration in the brain. The combination of LFAB and flucytosine has demonstrated synergism in vitro, and flucytosine achieves excellent CSF concentrations, making combination therapy attractive. Limited experience with the echinocandins has revealed both treatment successes and failures, in addition to breakthrough CNS infections after therapy for candidemia. The echinocandins have poor CSF penetration, with low levels compared with serum.[74] As a result, this antifungal class is not recommended for CNS candidiasis. Current recommendations for treatment of *Candida* CNS infection are to administer intravenous LFAB 3 to 5 mg/kg/day with or without flucytosine 25 mg/kg four times daily for the initial several weeks of treatment, followed by step-down therapy with fluconazole 6 to 12 mg/kg/day once treatment response to LFAB has been established. Therapy should continue until all signs and symptoms have resolved, including CSF and radiographic abnormalities. Removal of infected intracranial devices is strongly recommended.[224]

Ocular Candidiasis

No prospective studies exist for the treatment of *Candida* endophthalmitis; however, most experience has been with intravenous and/or intravitreal AmBd with or without flucytosine. Currently, AmBd 0.7 to 1 mg/kg/day combined with flucytosine 25 mg/kg four times daily is recommended for severe endophthalmitis (e.g., advancing lesions or lesions threatening the macula). For less severe cases, fluconazole 12 mg/kg on day 1 followed by 6 to 12 mg/kg/day may be administered. LFAB and voriconazole are reasonable alternatives. Early surgical intervention with partial vitrectomy may preserve vision in advanced cases. Intraocular instillation of antifungal agents is commonly practiced and may be of benefit. The optimal duration of antifungal therapy is not determined, but at least 4 to 6 weeks of system treatment is recommended, with continuation until all clinical evidence of intraocular infection has resolved.[224]

Chronic Disseminated Candidiasis

Treatment recommendations for chronic disseminated candidiasis are based on case reports and series; however, most clinical experience has been with AmBd, LFAB, and fluconazole. In clinically stable patients, fluconazole 6 mg/kg/day is recommended. LFAB 3 to 5 mg/kg daily or AmBd 0.5 to 0.7 mg/kg/day can be used to treat acutely ill patients or patients nonresponsive to fluconazole, either as a 1- to 2-week induction period before fluconazole step-down or as single therapy. Intravenous caspofungin given as a loading dose of 70 mg/m^2 on day 1 followed by 50 mg/m^2 daily are alternatives.[224] Therapy for chronic disseminated candidiasis is typically prolonged with a median duration of more than 3 to 5 months[193] and should continue until all lesions resolve or calcify. Continuation of chemotherapy has been shown to be safe in these patients, and stem cell transplantation may be performed if indicated in patients whose disease is controlled.[39,332] Adjuvant corticosteroid therapy in addition to antifungal therapy has been proposed, in light of the proposal that CDC represents a type of immune reconstitution inflammatory syndrome. Prednisone 0.5 mg/kg/day for at least 3 weeks was shown to result in rapid fever resolution in a single case series,[175] but more data are needed before corticosteroids can be recommended for this indication.

NEONATAL CANDIDIASIS

Epidemiology

Neonatal candidiasis in neonatal intensive care units (NICUs) remains a serious health problem because it is associated with substantial morbidity and mortality. Strategies for prevention and management of invasive *Candida* infections are paramount for improving outcomes for neonates.[32,33,148,298,347] The incidence of candidiasis increased in the NICU as advances in medical therapy allowed for increased survival of extremely low-birth-weight (ELBW; <1000 g at birth) and

low-gestational-age preterm neonates between the 1980s to 1990s; it then remained stable until 2001, when a decrease in the incidence was noted in infants weighing less than 1000 g owing to such factors as antifungal prophylaxis, antibiotic and medication stewardship, and central line–associated bloodstream infection (CLABSI) bundles.[57,96,164] Invasive infections occur in two main groups in the NICU—the extremely premature infant and any NICU patient with complex gastrointestinal disease (e.g., necrotizing enterocolitis [NEC], gastroschisis, and spontaneous bowel perforation).[33,87,265]

C. albicans and *C. parapsilosis* infections account for 80 to 90 percent of neonatal invasive candidiasis in centers not using antifungal prophylaxis.[33] Centers using fluconazole prophylaxis have very few infections, with the majority due to non–*C. albicans* spp. Less common *Candida* spp. include *C. glabrata* and *C. tropicalis*, and a small percentage of infections are due to *C. lusitaniae*, *C. guilliermondii*, and *C. dubliniensis*.

Invasive candidiasis in the neonate includes congenital cutaneous candidiasis and late-onset cutaneous candidiasis, BSIs, UTIs, meningitis, peritonitis, and infection of other sterile sites (e.g., bone and joint infections). These infections can be classified similar to other neonatal infections into early-onset (<72 hours after birth) and likely vertically transmitted and late-onset (≥72 hours after birth) and potentially horizontally transmitted infections.

There is variation between rates in different NICUs and incidence reported in the literature based on patient demographics, use of antifungal prophylaxis, surgical population, resuscitation of extremely preterm infants, and feeding, medication, and antibiotic practices in individual NICUs. Fridkin and associates reported the rate of *Candida* BSIs ranged from 3 percent to more than 23 percent among NICUs in infants weighing less than 1000 g, and other researchers have reported similar findings.[33,67,96] Centers that care for infants with gastroschisis, NEC, and other complex gastrointestinal diseases have an increased risk for invasive candidiasis.[87] Resuscitation practices may be the most significant area of practice variation affecting invasive candidiasis rates. NICUs in which the practice is not to resuscitate infants who are less than 25 weeks' gestational age would have a lower rate of invasive candidiasis in infants weighing less than 1000 g, compared with centers caring for 23- and 24-week gestation infants.

Studies including all invasive candidiasis in both preterm and full-term infants are rare, and most studies of incidence or risk factors focus on *Candida* BSIs. If candidemia alone is examined, the largest amount of data comes from a report from 128 United States NICUs using U.S. National Nosocomial Infections Surveillance (NNIS) system data from 1995 to 2004 (n = 130,523 neonates).[96] For infants weighing less than 1000 g, the median infection rate was 7.5 percent, whereas 25 percent of NICUs had rates of 13.5 percent or higher. The incidence decreases significantly for infants weighing more than 1000 g. Candidemia rates for infants with birthweights from 1001 to 1500 g are 1.32 percent, from 1501 to 2500 g, 0.36 percent, and more than 2501 g, 0.29 percent. The incidence increases in an inverse linear pattern, from around 3 percent at 28 weeks' gestation to 24 percent at 23 weeks' gestation.

Candida CLABSIs among NICUs from 1999 through 2009 have decreased from 0.92 to 0.2 per 1000 catheter-line days.[57] These are data from all birth weight groups in the NICU, with infants weighing less than 1000 g representing nearly 70 percent of these infections. CLABSIs due to *C. albicans* decreased from 0.53 to 0.09 and those from non–*C. albicans* infections from 0.39 to 0.1 per 1000 catheter-line days.

The incidence of invasive candidiasis in ELBW infants, not including congenital cutaneous candidiasis, is around 10 percent. The highest incidence of invasive candidiasis occurs in the most extremely preterm infants and is greater than 20 percent for infants of less than 25 weeks' gestation (Fig. 199-1).[33] *Candida* UTIs account for an additional 3 to 4 percent of invasive candidiasis in ELBW infants.[33,144,336] Two recent multicenter studies have reported that *Candida* UTIs have a high associated mortality that is similar to that for *Candida* BSIs in ELBW infants, thus confirming their invasive nature in neonates.[33,256] Finally, meningitis and peritonitis contribute

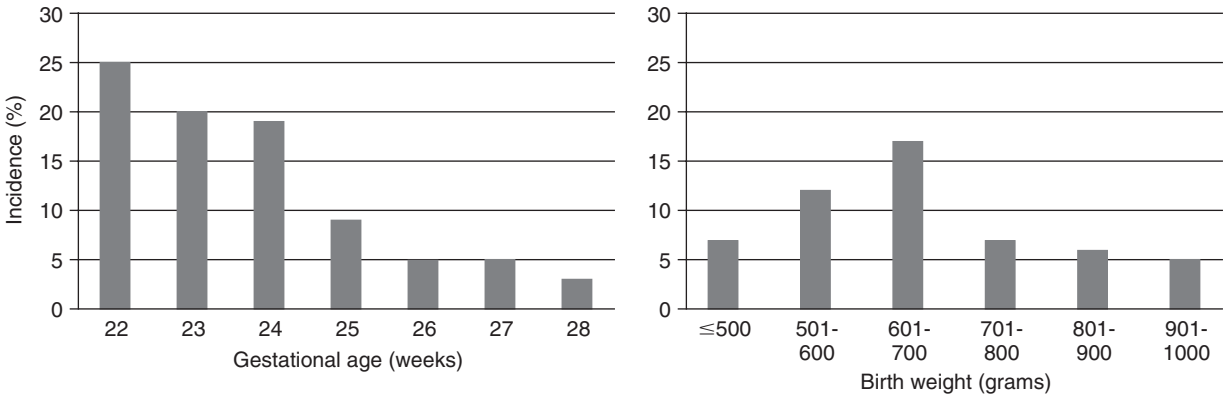

FIGURE 199-1 ■ Invasive *Candida* bloodstream infection, urinary tract infection, meningitis, or peritonitis in infants weighing less than 1000 g birth-weight not receiving antifungal prophylaxis. Gestational age has a linear relationship to invasive candidiasis compared with birth-weight and aids in defining the highest risk patients. (Data from 137 infections in 1515 infants weighing less than 1000 g from 19 centers of the National Institute of Child Health and Human Development [NICHD] Neonatal Research Network.)

an additional 1 to 2 percent of invasive candidiasis in ELBW infants.

The literature has limitations on defining incidence. In a study from the United Kingdom, a 2.1 percent incidence was reported in infants weighing less than 1000 g but antifungal prophylaxis was not ascertained. These researchers subsequently studied the use of antifungal prophylaxis and found that almost 30 percent of NICUs were using antifungal prophylaxis, which may account for the lower reported rates of infection.[60,61] Such studies illustrate how infection rates may be higher than what is reported in the literature if all data, medications, and risk factors are not captured.

Complex gastrointestinal diseases can be complicated by invasive candidiasis. Patients with NEC, focal bowel perforation, and gastroschisis have a high incidence of invasive candidiasis. Feja and colleagues found that candidemia was increased in patients with gastrointestinal pathologic processes (OR, 4.57; 95% CI, 1.62 to 12.92).[87] Gastrointestinal pathologic processes were defined in their study as tracheoesophageal fistula, gastroschisis, omphalocele, Hirschsprung disease, intestinal atresias, or episodes of NEC. Other studies have found the incidence of invasive candidiasis in patients with NEC is more than 10 percent. After combining data from studies by Noyola and associates[216] and Chapman and Faix,[53] the incidence of candidemia is 16.5 percent in patients with NEC. Focal bowel perforation, which occurs primarily in infants weighing less than 1000 g, is associated with a 50 percent incidence of invasive candidiasis, the majority of cases being *Candida* peritonitis.[62,247]

Infants with congenital heart disease are an emerging patient population who may develop invasive candidiasis. According to Ascher and associates,[11] candidemia accounts for 9 percent of BSIs in patients with congenital heart disease cared for in NICUs in the first 4 months of life; *Candida* BSI occurred at a rate of 6.3 per 1000 admissions and had an overall mortality rate of 21 percent.

Candida spp. are the second most common cause of infection in neonates on extracorporeal membrane oxygenation (ECMO).[38] Compared with the first 7 days on ECMO, infections are twofold and fourfold more common between days 8 and 14 and after 14 days on ECMO, respectively.

Risk Factors

Because neonatal candidiasis can be fatal among premature infants, an understanding of the risk factors that lead to infection is critical. Conditions that facilitate fungal colonization and proliferation and increase the risk for invasive infection include gastrointestinal dysmotility or ileus, antibiotics, acid inhibition, corticosteroids, and the immaturity of the patient's immune system. Several risk factors have been identified, with gestational age having the strongest effect. This correlates with the degree of the underdeveloped immune system, skin, respiratory, and gastrointestinal tracts in these infants.

The immature lymphocyte and antibody system predisposes preterm infants to skin and mucosal fungal colonization, whereas deficient neutrophil and innate host defense mechanisms predispose them to dissemination and overwhelming infection.[146] With compromise of the barrier defense system, invasive candidiasis may occur because of deficient neutrophil number and function. Neutrophils provide the major role in antifungal defense, ingesting and killing *Candida* in a process requiring production of oxygen metabolites, antibodies, and cytokines and activation of the C3 complement component, all of which are decreased in preterm infants compared with term infants and adults. Also deficient are neutrophil granules and cytokines, which play a critical role in the lysis of *Candida* hyphae and pseudohyphae, which are too large to be engulfed by phagocytosis. Macrophages have impaired adherence, phagocytosis, and oxidative killing in preterm infants, thus affecting their ability to contain fungal colonization and infection. In addition to cell-mediated defenses, cytokines contribute to innate immunity against fungal infection through enhancement of cell-mediated fungicidal activity. Pulmonary host defense is primarily through alveolar macrophages, cilia and mucus, and surfactant, all of which are deficient in preterm infants.

Risk factors for *Candida* colonization and sepsis are similar.[264,265] Colonization of the skin, mucosal membranes, and/or vascular catheters commonly precedes infection. Biofilm formation on catheters inhibits the host's defense mechanisms and the penetration of antifungal agents. Using sterile precautions in preparation of parenteral nutrition, intravenous fluids, and medications and when performing line changes at the bedside is critical for infection control. Infusates may also become contaminated and directly seed the bloodstream. In vitro growth curves demonstrate that *Candida* spp. have a selective growth advantage compared with bacteria in parenteral nutrition fluid.[171] Invasive candidiasis is usually preceded by prior colonization, which may occur via vertical or horizontal transmission. Most fungal colonization occurs by 2 weeks of life.[21,130,261] Fungal colonization of the skin, respiratory tract, or gastrointestinal tract occurs in 10 percent of full-term infants compared with 26.7 to 62.5 percent of those of very low birth-weight (VLBW; <1500 g at birth) in the first weeks of life.[146] Fungal colonization and subsequent infection depends on exposure, size of inoculum, host susceptibility, and properties of the pathogen (Fig. 199-2).

Vertical transmission leading to colonization often occurs. *Candida* yeast cells adhere preferentially to intermediate layers of the vaginal tract that are increased during pregnancy, increasing maternal fungal colonization and exposure of vaginally delivered infants. The incidence of vaginal fungal colonization during pregnancy has been reported to be between 25 and 50 percent, with 85 to 90 percent due to *C. albicans* and the remainder predominantly *C. glabrata* and *C. tropicalis*.[146] Despite the frequent fungal colonization, chorioamnionitis caused by *Candida* is a rare event, with almost all vertical transmission occurring when the infant passes through the birth canal via mucocutaneous contact, swallowing, or aspiration of fungi.[195,338] Treatment of maternal *Candida* vaginosis and UTIs during pregnancy may decrease the inoculum the infant is exposed to and potentially prevent vertical transmission.[94,146]

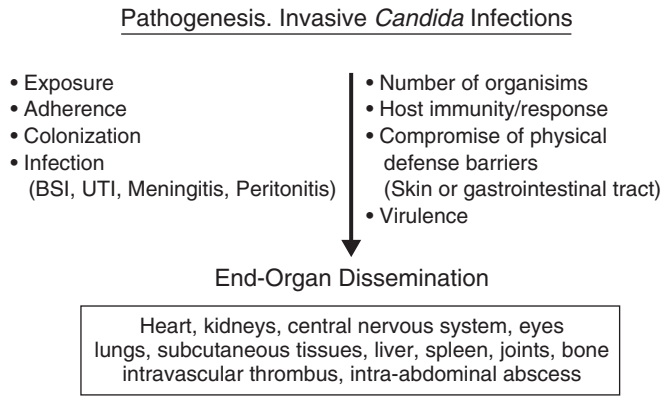

FIGURE 199-2 ■ Pathogenesis of invasive candidiasis.

Candida colonization also may be acquired horizontally, primarily from the hands of health care workers. In a multicenter trial examining fungal colonization in six NICUs, *Candida* spp. were isolated on the hands of 29 percent (859 of 2989) of health care workers.[264] Although *C. albicans* was the more common fungal isolate in all NICU patients (14% vs. 7%), *C. parapsilosis* was the most common species isolated from the hands of NICU staff. *C. parapsilosis* was isolated from 19 percent (similar to a single-center incidence of 20 percent), and *C. albicans* was isolated from 5 percent of the cultures from health care personnel (p <.001). *C. lusitaniae* (2%), *C. guilliermondii* (1%), *C. tropicalis* (<1%), and *C. glabrata* (<1%) were also recovered from hand cultures. Increased handling required by sicker preterm infants increases the risk for acquiring fungal colonization from health care workers' hands, contaminated infusates, and catheters or catheter-related devices because there are an average of 32 direct touches to an infant during a 12-hour shift.[63,264]

Candida spp. causing invasive infection rarely colonize environmental sources.[20,272] Despite the tendency of fungus to grow in moist environments, studies have not isolated fungi from isolettes, incubators, wash basins, water faucets, chest tubes, intravenous drug pumps, ventilators, pumped breast milk, inanimate objects, or radiant warmers.

The skin and gastrointestinal tract are the most common sites for *Candida* colonization.[20,144] Colonization is inversely proportional to gestational age, and fungal colonization occurs on the skin and gastrointestinal tract before the respiratory tract. Colonization at two or more sites occurs similarly with *C. albicans* (77%) and *C. parapsilosis* (85%), whereas colonization at three or more sites occurs more frequently with *C. albicans* (69%) compared with *C. parapsilosis* (23%) (p = .047).

Candida spp. produce proteases that may be lytic for the thin keratin layer produced by the immature stratum corneum and phospholipases against lipid membranes that both may facilitate epithelial invasion.[81,146] Increased transepidermal water loss from preterm skin creates a moist environment that facilitates fungal colonization and growth. Because of the increased permeability of the preterm skin, substrates such as glucose may diffuse to the epithelial surface, facilitating *Candida* growth. *Candida* may alter its surface structure in the presence of high glucose, thus increasing its adherence and proliferative properties. A thicker keratin layer is produced by 2 weeks of life in the extremely preterm infant, after which new fungal skin colonization occurs less frequently.

The microflora of the gastrointestinal tract plays an important role in fungal colonization and infection. Buccal candidal adherence is increased in preterm compared with term infants, facilitating colonization.[68] A normal bacterial flora inhibits *Candida* growth by competing for both adhesion sites and nutrients.[122,154] In a study of athymic mice given an oral challenge with *Candida*, fungal colonization was attenuated in mice with a normal gut flora compared with those with a germ-free microflora.[122] This highlights the fact that the intestinal microflora may be as important as an intact immune system in preventing fungal colonization.

Although skin and gastrointestinal colonization are more common and precede respiratory tract colonization, endotracheal colonization has a higher risk for infection.[152] Rowen and associates demonstrated that with endotracheal fungal colonization candidemia was 15.4 times more likely to occur than when infants were without any fungal colonization.[261] After controlling for fungal colonization at other sites was done, endotracheal colonization alone increased the risk for fungal sepsis 5.9-fold. (95% CI, 1.34 to 26).

When risk factors are examined by species, central vascular catheters, vaginal delivery, use of third-generation cephalosporins, and high acuity are the risk factors for *C. albicans* infection.[265] Histamine type 2 (H_2) antagonists, third-generation cephalosporins, central vascular catheters, parenteral nutrition and lipid emulsions, and high acuity are risk factors for *C. parapsilosis* infection. Gastrointestinal disease, exposure to fluconazole or antibiotics, prolonged hospitalization, and infection with other fungi increase the risk for sepsis due to *C glabrata*. Gastrointestinal mucosal injury, antibiotic suppression of bacterial flora, neutropenia, and parenteral nutrition increase the risk for sepsis due to *C. tropicalis*.

Medications such as broad-spectrum antibiotics and third- and fourth-generation cephalosporin and carbapenem antibiotics are associated with increased risk for candidemia.[29,67,265] It is hypothesized that these medications accumulate in high concentrations in an infant's bile and alter the balanced gastrointestinal microflora, eradicating competitive gram-negative and anaerobic bacteria and thus facilitating proliferation and dissemination of fungal organisms. Other classes of drugs found to be risk factors for neonatal fungal infection are H_2 antagonists and postnatal corticosteroids.[265,299] In infants weighing less than 1000 g, an association between lack of enteral feedings and infection has been reported.[32] For infants not feeding by the third day of life, 8.7 percent developed *Candida* BSI or meningitis, compared with 3.4 percent of those receiving enteral feedings.

Feja and associates examined risk factors in 2001 through 2002 and using multivariate analysis found that catheter use (OR, 1.06 per day of use; 95% CI, 1.02 to 1.10), previous bacterial BSIs (OR, 8.02; 95% CI, 2.76 to 23.30), and gastrointestinal pathologic processes as mentioned previously (OR, 4.57; 95% CI, 1.62 to 12.92) were significantly associated with candidemia.[87]

The extremely preterm infant has the unique combination of being immunocompromised (including an immature skin and gastrointestinal tract), requiring prolonged intensive care (parenteral nutrition, mechanical ventilation, central venous access), being exposed to medications that promote fungal growth (H_2 blocking agents, proton pump inhibiting agents, postnatal corticosteroids, and broad-spectrum antibiotics), and predisposed to gastrointestinal dysmotility and disease (NEC and focal bowel perforation).[33,87,265] Infants with complicated gastrointestinal diseases such as gastroschisis or NEC have combined risk factors of prolonged ileus, central venous access, parenteral nutrition, surgery, and exposure to prolonged and/or broad-spectrum antibiotics.[87]

Pathogenesis

Adherence and the slow-growing nature of *Candida* facilitate its ability to colonize and disseminate into the bloodstream and body tissues before clinical signs and symptoms of infection become apparent. Surface glycoproteins play a role in fungal adherence. One such surface adherence glycoprotein is INT1, which binds to β-integrins present on the endothelium and white blood cells. The absence of a functional INT1 gene diminishes adherence in yeast cells but not filamentous forms.

The preterm infant is immunocompromised and frequently exposed to broad-spectrum antibacterial medications. Investigators have studied the effect of corticosteroids and antibiotics in mice orally inoculated with *C. albicans* to mimic conditions in the preterm infant.[28] Antibiotic treatment alone led to increased *Candida* colonization but did not affect dissemination. When dexamethasone was added to the antibiotic regimen (presumably amplifying the inherent immunoincompetence), both colonization and dissemination increased in these animal models. Dexamethasone plus antibiotics led to an increase in the percentage of filamentous forms in the gastrointestinal tract compared with antibiotics alone. In addition, introduction of *C. albicans* strains with two functional copies of the INT1 gene increased the number of fungi colonizing the cecum and disseminating to extraintestinal sites.

C. albicans is dimorphic, having both yeast and filamentous forms (e.g., hyphae, pseudohyphae, germ tubes), and is assumed to have increased virulence in immunocompromised patients because of the filamentous forms. Filamentous forms may contribute to colonization and infection, although species that do not form filaments, such as *C. glabrata*, also can colonize and cause invasive disease in preterm infants.

To further examine the role of yeast and filamentous forms, researchers intravenously or orally infected antibiotic-treated and dexamethasone-treated mice using three strains of *C. albicans:* (1) a wild-type strain that had both yeast cell and filamentous forms, (2) a strain with only yeast cells, and (3) a strain that was constitutively filamentous.[27] The mortality rate was significantly greater in both the wild-type (92%) and yeast-cell (56%) strains compared with the filamentous strain alone (0%). The filamentous strain had no dissemination, and cecal colonization was significantly less than that of the other two strains. The wild-type strain had diffuse hyphal invasion with increased tissue necrosis compared with the yeast-cell strain. The researchers speculated that the yeast forms are critically important for adherence and tissue dissemination and that hyphal formation in the tissues contributes to parenchymal destruction.

Clinical Manifestations

Congenital Cutaneous Candidiasis

Congenital cutaneous candidiasis may manifest as pustules, vesicles, skin abscesses, and/or an erythematous maculopapular rash when the patient is born (or within a few days after birth) (Table 199-2, Fig. 199-3). The skin involvement covers one or more of the following areas: face/scalp, chest, abdomen, perineal area, one or more extremities, and/or the back. These lesions occasionally lead to desquamation. VLBW infants with congenital *Candida* infection are more likely to have severe infection, such as pneumonia and widespread dermatitis with focal areas of superficial erosion and desquamation. Dissemination can also occur in term infants (~10%), so treatment should be for 14 days. For affected term infants, it is reasonable to discuss the need for evaluation of the infant's immune system for a primary immunodeficiency. ELBW infants with congenital cutaneous candidiasis are at greater risk for developing dissemination to blood, urine, or CSF (66%) compared with those weighing 1000 to 2500 g (33%) or term infants (11%). For this reason, all should be treated with systemic antifungal therapy.

The skin involvement with congenital cutaneous candidiasis is invasive with a high burden of yeast and should be treated similarly as for other invasive fungal infections. Dissemination occurs if the infection is not treated for 14 days. In a study examining the pathogenesis and pathology of these infections, skin biopsies demonstrated invasion into the epidermis, with an inflammatory process ranging from dermal invasion and granuloma formation to focal necrosis and hemorrhage.[260] These data from biopsies give insight into the invasive nature of cutaneous involvement, demonstrating that these infections are invasive and need prompt intravenous antifungal therapy. Routine aerobic skin culture will isolate organisms causing rash (skin biopsies are not needed). By culturing for both fungal and bacterial organisms, the source of infection can be determined promptly and treatment started in a timely fashion. Differential diagnosis includes staphylococcal, other bacterial, and other fungal skin infections. Pathologic study with fungal staining of the umbilical cord and placenta can also aid in diagnosis.

Cutaneous Candidiasis

Cutaneous candidiasis, referred to in the past in the literature as mucocutaneous infection, occurs later than congenital cutaneous candidiasis and at the same time as late-onset sepsis, at between 2 and 3 weeks of age.[83] The incidence in one study reported an incidence of 7.8

TABLE 199-2 Neonatal Cutaneous Candidiasis Definition

Definition: Extensive *Candida* Rash Covering Two or More Affected Areas

Affected Areas

Skin
Chest
Abdomen
Back
Extremity
Groin or perineal area
Neck
Face or scalp
Umbilical cord and placenta
  White plaques on umbilical cord
  Placenta with yeast invasion

Timing

Congenital cutaneous candidiasis: presents in the first 48 hours of life and usually present at birth
Cutaneous candidiasis: presents after 2 to 7 days of life

Rash

Maculopapular
Scaly, erythematous
Dry flaking
Desquamating
Burnlike erythematous

Presentation

Extensive
Covering two or more affected areas
Covering one affected area *plus* umbilical plaques or placental pathology (silver or hematoxylin and eosin) would count as one affected area

Evaluation

Congenital cutaneous candidiasis: culture rash sites, send placental and/or cord for culture and pathology with silver stain for yeast; blood culture and cerebrospinal fluid culture (unless rash over lumbar area, if so treat empirically for meningitis)
Cutaneous candidiasis: Culture rash sites, blood, urine, and cerebrospinal fluid (unless rash over lumbar area, if so treat empirically for meningitis)

Diagnosis

Extensive Rash plus 1 or more of the following:
  Surface culture isolating *Candida* species
  Placental or cord identification (culture or silver stain) of yeast or *Candida* species for congenital cutaneous candidiasis
  Positive blood, urine, cerebrospinal fluid cultures for *Candida* species

Treatment

14-day course of intravenous antifungal therapy for end-organ dissemination

percent in VLBW infants in the era before antifungal prophylaxis.[83] Cutaneous candidiasis can also present as a diffuse burnlike erythematous rash that can be papulopustular and in some patients exfoliates. Risk factors include extreme prematurity, vaginal birth, postnatal corticosteroids, and hyperglycemia.[22,83,260] Cutaneous candidiasis is an invasive infection of the skin and needs prompt treatment for a minimum of 14 days in preterm infants. It also has a high rate of disseminating to the bloodstream and other fluids, and evaluation of blood, urine, and CSF is warranted.[22]

Neonatal Candidemia

Bloodstream infection with fungal species demonstrates clinical signs and symptoms similar to bacterial sepsis. The following signs and symptoms occur in the order of their prevalence with candidemia[86]; thrombocytopenia of less than 100,000/μL (84%), immature-to-total neutrophil ratio of greater than or equal to 0.2 (77%), increase in apnea and/or bradycardia (63%), oxygen requirement (56%), assisted ventilation (52%), lethargy and/or hypotonia (39%), gastrointestinal symptoms (e.g., gastric aspirates, distention, bloody stools) (30%), hypotension (15%), hyperglycemia (13%), elevated white blood cell count greater than 20,000/μL (12%), metabolic acidosis (11%), and absolute neutrophil count less than 1500/μL (3%). Most importantly, candidemia can be associated with disseminated disease. Evaluation for end-organ dissemination is warranted.

Neonatal Urinary Tract Infection

Evaluation of late-onset sepsis should include a urine culture obtained via sterile catheterization (or suprapubic bladder aspiration).[256] Signs and symptoms of UTIs can be similar to sepsis.[25] Additionally, an elevated creatinine value in absence of other pathologic processes should prompt evaluation for a UTI. If the urine culture is positive for fungus, renal ultrasonography should be performed to evaluate renal fungal abscesses. Candiduria develops in approximately 2.4 percent of VLBW infants and up to 6 percent of ELBW infants.[33,144] Recent studies have demonstrated similar mortality in infants with *Candida* UTI alone (26%) compared with *Candida* BSIs (28%) in ELBW infants.[33] Risk factors for candiduria in infants weighing less than 1000 g include vaginal birth, lower mean birth weight and gestational age, male sex, and receipt of prolonged initial empirical antibiotic therapy.[343] These findings emphasize the need for prompt treatment for a duration of 14 days.

Neonatal Meningitis

The reported frequency of fungal meningitis among VLBW infants is 1.6 percent.[207] The true incidence is likely higher because lumbar punctures are not obtained in many VLBW infants at the onset of sepsis.[297] Cell counts in preterm infants may not always be helpful because the results may not be abnormal in the presence of meningitis.[64,102] To reliably diagnose *Candida* meningitis, a lumbar puncture is needed before institution of antifungal therapy.

Neonatal Peritonitis

Invasive candidiasis can complicate the course of neonates with NEC or focal bowel perforation. Neonates with peritonitis secondary to bowel perforation due to NEC or focal bowel perforation often have abdominal

distention with or without erythema. In one study, *Candida* spp. were the predominant organism causing peritonitis in 15 percent of the perforated NEC cases and 44 percent of focal bowel perforation patients.[62] Radiographs help confirm perforation but at times may not be clear, and ultrasonography or an exploratory laparotomy may be needed if clinically indicated. When exploratory laparotomy is performed or drains are placed, cultures should be obtained to determine if *Candida* is associated with bowel perforation, peritonitis, and abscesses.

Neonatal Candida End-Organ Dissemination

At the time fungal infection is clinically apparent, the organisms have often disseminated from the blood, urine, or CSF to adhere and proliferate in body fluids, tissues, and organs. *Candida* spp. can cause endocarditis, endophthalmitis, dermatitis, peritonitis, osteomyelitis, and septic arthritis, and fungal abscesses may form in the CNS, kidneys, liver, spleen, skin, bowel, and peritoneum (Fig. 199-4). Fungal end-organ dissemination has been noted since the earliest reports of *Candida* sepsis in neonates. In an early review of 31 VLBW infants with invasive fungal infection (1972-1982), dissemination occurred to the bones or joints (26%), eye (23%), lung (13%), skin (10%), heart (6%), and peritoneum (3%).[134] More than one organ system was involved in 21 of these cases. The high prevalence of end-organ dissemination in older studies of neonatal fungal sepsis reflects prolonged periods of fungemia, because most of the diagnoses were made late or by autopsy. A meta-analysis of studies reporting fungal end-organ dissemination in neonates spanning both older and more recent practices from 1979 through 2002 found the median prevalence of cardiac vegetations or thrombi was 5 percent, with that of endophthalmitis 3 percent, of renal involvement 5 percent, and of CNS abscesses 4 percent.[30] In a more recent time period (1989-1999) of 86 cases of fungal sepsis in neonates, cardiac vegetations or thrombi occurred in 15.2 percent, endophthalmitis in 6 percent, renal involvement in 4.5 percent, and liver abscesses in 3 percent.[216] Dissemination may be higher in the lower birth-weight infant. In a study from 1988 through 1995 that examined 46 ELBW infants with fungal sepsis or meningitis, fungal abscesses of the CNS were found in 13 patients (28%).[97]

Noyola and colleagues[216] and Chapman and Faix[53] found that infants with candidemia for more than 5 and 7 days, respectively, were more likely to demonstrate ophthalmologic, renal, or cardiac abnormalities than those with a shorter duration of candidemia. When amphotericin B was administered and central vascular

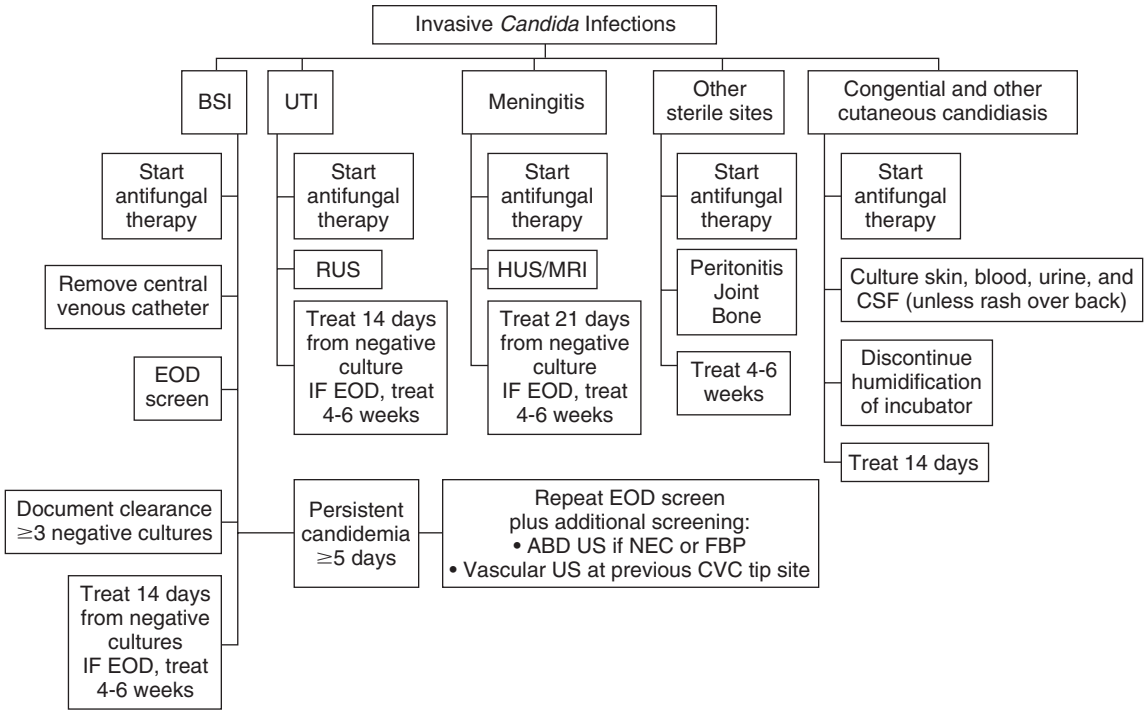

FIGURE 199-4 ■ Algorithm for evaluation and treatment of invasive *Candida* infections in neonates. Initial therapy pending susceptibilities: Amphotericin B deoxycholate (1 mg/kg/day). Alternatives: Amphotericin B lipid preparations (5 mg/kg/day) and fluconazole (12 g/kg/dose). With end-organ dissemination, meningitis, and persistent candidemia greater than 7 days, combination therapy with a second antifungal agent (fluconazole) is recommended. End-organ dissemination (EOD) includes performing an echocardiogram, renal ultrasonography (RUS), eye examination, and head ultrasonography (HUS). If bowel disease such as necrotizing enterocolitis (NEC) or focal bowel perforation (FBP), a complete abdominal ultrasound evaluation for abscess should be performed.

catheters were removed within 2 days of the first positive blood culture, outcomes such as end-organ dissemination and mortality were not increased.[216] With improved blood culture methods, the majority of blood cultures will grow *Candida* within 2 days and is associated with lower dissemination rates. One study of neonates demonstrated that isolation of fungus in blood cultures occurred at 37 ± 14 hours, and 97 percent of blood cultures were positive by 72 hours if the patient was not exposed to antifungal therapy.[273]

Neonatal Endocarditis and Infected Vascular Thrombi

Candida endocarditis has been reported in 5.5 to 15.2 percent of cases of fungal sepsis, with equal prevalence for *C. albicans* and *C. parapsilosis*. Fungal endocarditis may be associated with higher mortality than fungemia alone.[53,216] Use of central vascular catheters places neonates at increased risk for endocarditis and infected vascular thrombi. As discussed previously, they can cause local trauma to valvular, endocardial, or endothelial tissue, thus creating a nidus for thrombus and infection.

Neonatal Endophthalmitis and Retinopathy of Prematurity

Endophthalmitis begins as a chorioretinal lesion that gradually elevates and breaks free in the vitreous, appearing as a white fluffy ball. These solitary or multiple white lesions are most often seen in the posterior retina (zone I) and vitreous. In adults and children the clear cell-free vitreous becomes hazy, owing to an influx of inflammatory cells. This vitreous reaction is more difficult to recognize in preterm infants because of the vitreous haze that is present in the first weeks of life. The most immature infants appear to be at highest risk for fungal endophthalmitis. The incidence of retinal endophthalmitis with candidemia has decreased over the years, likely because of more rapid diagnosis and treatment. In a retrospective study from 1989 through 1999, 6 percent (4 of 67) of preterm infants with fungal sepsis who had indirect ophthalmoscopy had endophthalmitis.[216]

Even in absence of visible retinal abscesses or chorioretinitis there is some epidemiologic evidence that *Candida* sepsis may predispose preterm infants to severe retinopathy of prematurity. In a study of ELBW infants, threshold retinopathy of prematurity developed in 33 percent (19 of 58) of infants with a history of candidemia compared with 10 percent (39 of 391) without candidemia, but this was not statistically significant when controlled for gestational age.[139] Conversely, Noyola and colleagues,[215] in a case-control study of VLBW infants and those less than 28 weeks' gestation, found that 52 percent (24 of 46) of infants with candidemia developed threshold retinopathy of prematurity compared with 24 percent (11 of 46) of controls without candidemia (p = .008). Although the data regarding an association between fungal sepsis and retinopathy of prematurity are conflicting, early and frequent screening for retinal pathology is recommended in preterm infants with candidemia.

Neonatal Renal System and Fungal Infection

Candida UTIs may occur via the urinary tract as an ascending infection or dissemination via hematogenous spread. Renal factors that favor *Candida* growth include local immune factors and a delayed renal inflammatory response as well as hypertonicity and acidity of the tubular lumen. In preterm infants urine pH is increased in the first weeks of life owing to decreased bicarbonate reabsorption at the proximal tubule. Prematurity, antibiotics, and immunosuppressive therapy are also risk factors for renal fungal infections. In six studies of VLBW infants, the incidence of fungal UTI was 2.4 percent among all 1322 infants and 58.3 percent (28 of 48) in infants with fungal sepsis.[146] In one study of ELBW infants, the incidence of fungal UTI was 6 percent (3 of 50) and 1 of 8 infants with fungal sepsis had *Candida* UTI.[144]

Renal fungal abscess formation may complicate *Candida* UTIs in preterm infants. Fungal UTI may occur alone or in conjunction with fungal sepsis. Renal abscess formation in preterm infants may occur by dissemination of candidemia or as an ascending infection with candiduria. In one study, 41 of 8790 (0.5%) infants admitted to a NICU developed candiduria with median birth weight of 890 g and gestational age of 27 weeks.[45] Candiduria occurred in the more preterm infants, and renal abscesses developed in 36.6 percent (15 of 41) of the infants with candiduria. These 15 patients had a median birth weight of 770 g and gestational age of 26 weeks. Initial ultrasound examinations were normal in 6 patients, who developed renal abscesses 8 to 39 days later. This study suggests that in infants with candiduria, renal imaging studies should be performed at the time of infection and also at the end of antifungal treatment.

Neonatal Central Nervous System Candidiasis

Fungal infection of the CNS may result in meningitis, ventriculitis, or abscess formation in infants. Culture of the CSF is important in diagnosing fungal meningitis in infants because CSF cell counts and blood chemistry results may not be abnormal.[102] In one study of 25 infants with *Candida* sepsis or meningitis, CSF abnormalities occurred in only 25 percent of cases of culture-proven *Candida* meningitis.[174] In another study of VLBW infants with *Candida* meningitis detected by culture, the most common CSF abnormality was low glucose (<30 mg/dL), whereas the CSF protein level was elevated in only half of the patients (range, 30 to 480 mg/dL). CSF white blood cell counts ranged from 3 to 1030 cells/μL with varying percentages of neutrophils and mononuclear cells in these cases of culture-proven fungal meningitis.

Fungal abscesses of the CNS have been reported to be microscopic and not readily detectable by ultrasonography. In a study of 46 ELBW patients with fungal sepsis and/or meningoencephalitis, only 6 of 13 patients with fungal CNS abscesses had abnormal results on lumbar puncture.[97] Studies have found an association between invasive fungal infection and periventricular leukomalacia in preterm infants, possibly related to release of cytokines that may damage the periventricular white matter.[97] These findings and animal studies demonstrate the need for cranial imaging such as ultrasonography in all patients with fungal sepsis regardless of the results of CSF studies.[123]

Diagnosis

The majority (>99%) of fungal infections in neonates are due to *Candida* spp., the remainder are due to *Aspergillus* and *Zygomycetes*. Most common infections are of the blood, urine, skin, central nervous system, and/or other sterile body fluids. Dissemination can occur and screening for end-organ dissemination of abscess formation is warranted (see Fig. 199-4). Most commonly, with BSI, an initial screening including echocardiography, renal ultrasonography, cranial ultrasonography, and an ophthalmologic examination is needed. If there had been a significant bowel pathologic process such as NEC or focal bowel perforation, a complete abdominal ultrasound study should be performed to rule out peritoneal, liver, or spleen involvement. If signs and symptoms of septic arthritis (joint swelling) or osteomyelitis (swelling or immobility) are present, evaluation with joint aspiration, bone scan, or MRI is necessary. If candidemia persists, end-organ dissemination is even more likely and screening should be repeated as well as additional surveillance performed after 5 to 7 days, including (1) ultrasonography at the location of the tip of any central catheters for previous thrombus, (2) complete abdominal ultrasonography for abscesses (laparotomy is sometimes considered if there is high clinical suspicion), and (3) cranial ultrasonography/MRI to detect brain dissemination if meningitis. Treatment of invasive fungal infections in neonates requires intravenous administration of an antifungal agent and the removal of central venous catheters in infants with *Candida* BSIs.

Culture of blood, urine, CSF, and peritoneal fluid or other sterile body fluids remains the best method for diagnosing invasive *Candida* infections. Focus on obtaining sufficient blood culture volumes (≥1 mL) and performing urine and CSF cultures at the time of evaluation for sepsis remain critical to making a prompt diagnosis. Laboratory capabilities to culture fungi, identify *Candida* spp., and perform susceptibility testing are critical to diagnosis and management of invasive candidiasis.

Fungal PCR assay to detect the gene for 18S ribosomal RNA (rRNA) in VLBW infants has yielded promising results but requires additional study.[305] PCR results detect a broader number of infections because they not only detect patients with candidemia but are also positive in those with *Candida* peritonitis and candiduria.

In addition, investigators are examining the role of monitoring markers of fungal disease to diagnose and evaluate responses to antifungal therapy. These markers include β-glucan and mannan of the cell wall, anti-*Candida* antibodies, D-arabinitol (candidal metabolite), and fungal chitin synthase (assessed with PCR). These studies are challenging in neonates and need to studied in both non-infected colonized patients as well as infants with ICI.

Treatment and Prevention

Adequate dosing of antifungal therapy has been understudied in neonates and remains a critical issue. Most of

the literature lacks good data on dosing and outcomes, and we have likely been underdosing our patients, which may contribute to delayed clearance, treatment failures, and increased dissemination, morbidity, and mortality. In addition to dosing, prompt central line removal in patients with *Candida* BSIs is needed for clearance and to improve outcomes. Information on central line removal is often lacking, making it difficult to assess the efficacy of the antifungal agents being studied. In the area of pharmacokinetics, premature neonates, full-term neonates, pediatric patients, and adults often have different plasma clearance rates and drug half-lives, which affect dosing decisions as well as drug efficacy, safety, and toxicity.

Amphotericin B Preparations

Amphotericin B deoxycholate (AmBd) should be the first choice for treatment of invasive candidiasis owing to its excellent coverage for almost all *Candida* spp. causing invasive candidiasis in neonates, its low cost compared with the lipid preparations and other antifungal agents, its safety, and its better renal penetration compared with lipid preparations. This is the best choice for initial therapy, pending speciation. Almost all *Candida* spp. have favorable susceptibility to AmBd, whereas 97 percent of neonatal isolates are susceptible to fluconazole. When fluconazole is being used for prophylaxis in the NICU for any patient, a different antifungal agent should be used for treatment of invasive candidiasis in that NICU to decrease antifungal pressure that may lead to azole resistance.

AmBd should be started at 1 mg/kg and with lipid preparations (LFAB) at 5 mg/kg.[6,18,224] Serum electrolytes and urine output should be monitored as additional sodium and potassium supplementation is often required. Fluids and enteral feedings should be adjusted to maintain urine output of 2 ml/kg/hour. Several studies in the past decade have demonstrated no adverse renal or systemic effects of daily AmBd at 1 mg/kg. Linder and coworkers demonstrated that dosing of 1 mg/kg of AmBd (n = 34) did not affect renal function.[180] Creatinine levels in milligrams per deciliter remained unchanged from the start of treatment (0.8 ± 0.4), at 24 hours after beginning treatment (0.8 ± 0.4), and again at the end of therapy (0.6 ± 0.2). This is an important difference compared with older children and adults in whom infusion-related reactions and nephrotoxicity are frequent concerns with AmBd. Lower "test" dosages of AmBd are not needed in neonates, because adverse effects commonly seen in older patients do not occur in neonates. Moreover, lower dosages in neonates only delay the time to achieve optimal therapy and may contribute to morbidity and mortality by delaying clearance of *Candida* spp. If the initial treatment is ineffective, studies have demonstrated safety with dosing of AmBd increased to 1.5 mg/kg/day and LFAB to 7 mg/kg/day.[133]

A few retrospective studies have examined whether LFAB is better than AmBd, but none has shown superiority.[12,180] The major differences that still need to be evaluated in prospective studies include risk for phlebitis when given via peripheral intravenous line and whether AmBd has an advantage in treating UTIs and renal abscesses. Animal studies have demonstrated significantly higher renal concentrations of AmBd (when comparing 1 mg/kg dosing of each preparation), which has led most experts to recommend preference over lipid formulations for UTIs and renal candidiasis. None of the studies have compared optimal dosing of 1 to 1.5 mg/kg of amphotericin deoxycholate with 5 to 7 mg/kg of lipid preparations of amphotericin B. As mentioned previously, one major advantage of AmBd is cost, because it is significantly less expensive compared with LFAB.

Azole Antifungal Agents

Fluconazole has demonstrated similar efficacy to AmBd. Although AmBd is the treatment of choice in neonatal invasive candidiasis, fluconazole is used at some institutions. Fluconazole is readily bioavailable and has excellent tissue penetration. As mentioned earlier, fluconazole should be reserved and used primarily for prophylaxis and added when combination therapy is desired. Population pharmacokinetic study of fluconazole in 23- to 40-week-gestation infants younger than 120 days of age demonstrated that dosing in young infants requires adjustment for gestational age at birth and postnatal age to achieve therapeutic systemic drug exposures and that doses at the higher end of the recommended range (12 mg/kg) may yield better efficacy while the safety of this dosing awaits further clinical study.[329] Standard dosing of fluconazole for treatment of invasive candidiasis had previously been 6 mg/kg. Studies have also suggested that a loading dose may help achieve high levels rapidly.[239] With higher dosing, safety in relation to liver function, drug-drug interactions, and effect on fungal resistance should be monitored and studied.

Unlike fluconazole, voriconazole is mostly protein bound and also tends to accumulate in infants with renal insufficiency, and drug levels should be monitored. There is some concern for toxicity in neonates with a developing retina, and it has not been recommended or studied in neonates for the treatment of candidiasis. From a few case reports in the neonatal literature and the adult and pediatric data, suggested dosing is 6 mg/kg every 12 hours (for 24 hours), followed by 4 mg/kg every 12 hours with monitoring of serum hepatic enzymes weekly and drug levels obtained if possible.[93,210]

Echinocandin Agents

Neonatal data regarding echinocandins are just emerging. Early studies of caspofungin used doses of 1 to 5 mg/kg/day with variable efficacy at the lower doses and major toxicity at the high doses.[213,220,287] Pharmacokinetic data in neonates recommend dosing of 25 mg/m^2/day.[263] With any use currently, renal and liver function and electrolytes, including calcium and phosphorus, must be closely monitored and levels obtained if feasible. Micafungin pharmacokinetic and safety data point to a dose of 10 mg/kg/day, but only in a few patients with limited safety data.[31] Micafungin at high doses in animals and in one case report using 15 mg/kg in a preterm infant may have adverse effects.[156] All the echinocandins need to

address four major issues: optimal dose, resistance patterns with regard to *C. parapsilosis*, safety, and CNS penetration.[123,232,281]

Combination Antifungal Therapy

Linder and associates reported on the outcomes with combination therapy.[180] A second antifungal agent, most commonly fluconazole, was administered in cases of fungal sepsis, initially with the presence of any abscess, a positive urine culture, or after 10 days of persistent culture-positive infection. Patients were treated for 14 days after negative culture or more until radiographic resolution of abscess if present. Information on central line removal was not included. Sterilization occurred in 36 patients (67%) with monotherapy and increased to 52 patients (96%) with polytherapy. Currently, combination antifungal therapy is not recommended for neonatal candidiasis as the initial treatment but could be considered with persistent candidemia after 7 days of antifungal treatment or meningitis. Pediatric infectious disease consultation may help facilitate optimal management of these cases when combination therapy is considered.

Central Venous Catheter Removal with Bloodstream Infection

The question of whether the removal of central venous catheters with *Candida* BSI on presentation of infection improves outcomes has been the subject of multiple studies. Several studies have demonstrated prompt removal is associated with lower mortality rates, a shorter duration of infection, and reduced end-organ dissemination.[32,53,140,216] National Institute of Child Health and Human Development (NICHD) Neonatal Research Network data showed that mortality was reduced from 37 to 21 percent (p <.024) when catheters were removed promptly (<24 hours) compared with delayed removal.[32] The combined outcome of neurodevelopmental impairment and death was associated with delayed removal/replacement of catheters; although there was a trend, no difference in neurodevelopmental impairment alone was observed (45% prompt removal vs. 63% delayed; p = .08). The strongest effect of prompt catheter removal and mortality was with *C. parapsilosis*, in which case after prompt removal 10 percent of patients died compared with 31 percent when catheter removal was delayed.

Catheter removal, not simply catheter replacement, is recommended.[216] *Candida* can quickly form resilient biofilms on catheters and prevent the penetration of antifungal agents. The recommendation, therefore, is prompt catheter removal until clearance of *Candida* infection from the blood is documented with three or more cultures. Further study of catheter replacement at a different site is needed but may be an option when peripheral intravenous access cannot be maintained or central access is needed for medications such as vasopressors. It is better to immediately remove and replace the catheter rather than delay removal if intravenous access is a major concern.

Duration of Candidemia

Another controversial issue regarding neonatal candidiasis is how to determine that a patient's bloodstream is clear of infection. The NICHD Neonatal Research Network investigated complete clearance of BSI and found that intermittent negative cultures were obtained between positive cultures in 21 percent of cases of infants with *Candida* BSI.[32] Possible explanations may be the nature of clearing *Candida* infections, the theory that all infections have undetectable microabscesses that may be slowly dissolving, and/or low volume of blood (<1 mL) sent for culture. Based on this high incidence of false-negative results, daily blood cultures of 1 mL or more should be drawn until three negative cultures are documented, to confirm sterilization of the bloodstream; then a new central access device can be placed. Treatment is recommended for 14 days after the bloodstream is clear of candidemia.[180]

Adjunctive Therapies

Infection is affected by fungal load, virulence, and host factors, with neutrophil function being critical for *Candida* killing and clearance. Neutropenia should be corrected in the presence of active infection if persisting after 2 days of antifungal therapy. As an adjunctive therapy for invasive candidiasis in the absence of neutropenia, therapy with granulocyte colony-stimulating factor, other colony-stimulating factors, and immunoglobulins has not demonstrated efficacy.[44,146]

Empirical Therapy. The value of empirical therapy and its ability to improve outcomes in neonatal candidiasis continues to be investigated. Antibacterial agents are routinely prescribed when clinicians are concerned about late-onset sepsis in neonates, and perhaps in certain cases antifungal agents also should be added, pending culture results. Some studies have suggested that empirical antifungal therapy may lower mortality and improve outcomes in VLBW infants with fungal sepsis, but this has not been investigated in controlled trials.[29,185] One retrospective study reported the results of empirical antifungal therapy in neonates weighing less than 1500 g and considered "very sick" in the NICU.[243] Empirical antifungal therapy was started in those high-risk patients who had received vancomycin plus a third-generation cephalosporin for 7 days and had one or more of the following infection risk factors: total parenteral nutrition, mechanical ventilation, corticosteroid use, H_2 blocking agents, or signs of a *Candida* rash or thrush. The authors reported *Candida*-related mortality in 11 of 18 (61%) patients who did not receive empirical therapy compared with none of 6 (0%) patients receiving empirical therapy, suggesting that empirical therapy may have a role in improving mortality outcomes.

Retrospective studies have suggested that empirical antifungal therapy may lower mortality and improve outcomes in preterm infants with fungal sepsis. Although empirical or prompt standardized treatment (including prompt removal of central vascular catheters) may reduce *Candida*-related deaths, neurodevelopmental impairment

may still occur in almost 60 percent of the survivors, particularly those with birth weight less than 1000 g.[32,109] More prospective studies controlled for timing, dose, antifungal agent used, and central line removal need to be performed. In NICUs that are successful in infection prevention, infections are viewed as preventable and focus is placed on prevention instead of early detection and treatment.[79]

Preemptive Treatment

Preemptive antifungal treatment has been proposed in a few neonatal studies when early detection of colonization with *Candida* or mannan is isolated in endotracheal tubes.[240,325] As covered in the colonization section, the lung is a high-risk site for colonization. With this approach of early identification followed by 14 days of antifungal treatment, invasive candidiasis was reduced from 23 to 0 percent of these patients with *Candida* identified in their respiratory tracts. This may be an approach to be studied in patients with NEC in whom *Candida* is isolated in the gastrointestinal tract.

Prevention

As with other infectious diseases, prevention is key to achieving the best clinical outcomes. Mortality and morbidity is high, and for ELBW infants 73 percent either do not survive or survive with neurodevelopmental impairment.[33] To date, antifungal prophylaxis is the only intervention that has been subjected to evidence-based randomized, controlled trials for the prevention of invasive candidiasis. A summary of neonatal fluconazole and nystatin prophylaxis studies has been recently reviewed.[149]

Prophylactic antifungal therapy has been shown to reduce both colonization and invasive candidiasis in high-risk preterm infants. At birth, most infants are not colonized or have low colony counts of yeast, making them ideal candidates for antifungal prophylaxis. In the absence of antifungal prophylaxis, up to 60 percent of ELBW infants become colonized in the first 2 to 3 weeks after birth.[144] Prophylaxis prevents invasive candidiasis by decreasing *Candida* colonization of the skin, gastrointestinal and respiratory tracts, and central venous catheter as well as colonization at multiple (two or more) sites.[14,144,187,190] Additionally, subinhibitory concentrations of fluconazole improve white blood cell phagocytosis and killing of *C. albicans* from 50 to 90 percent.[119]

Fluconazole

Currently there are more than 20 studies examining fluconazole prophylaxis for the prevention of invasive candidiasis in more than 5000 neonates that are consistently demonstrating efficacy, with an overall reduction in invasive candidiasis of more than 80 percent and a 90 percent decrease in *Candida*-related mortality.* The overall incidence of invasive candidiasis in the placebo or control (untreated) groups was 9.1 percent compared with 1.3 percent in the fluconazole prophylaxis groups (p <.0001).[153]

Efficacy is highest in the smallest (<1000 g) and youngest infants (≤27 weeks' gestation) when prophylaxis is started shortly after birth and given to all high-risk patients. All of these studies have demonstrated the safety of fluconazole prophylaxis and lack of emergence of resistance.[144,145,149,150,188]

The first study of fluconazole prophylaxis against fungal colonization and infection in preterm infants was a prospective, randomized, double-blind clinical trial involving 100 high-risk preterm ELBW infants who required central venous access or endotracheal intubation.[144] Infants were randomly assigned during the first 5 days of life to receive either 3 mg/kg fluconazole intravenously or placebo for up to 6 weeks. Results demonstrated that fluconazole prophylaxis significantly decreased invasive fungal infection. None of the infants in the treatment group developed infection compared with 20 percent of infants in the placebo group (p = .008). A subanalysis of infants younger than 24 weeks of gestational age, approximately 10 percent of the cohort, revealed that fluconazole treatment was efficacious even in the most immature of infants.

From a system's viewpoint, the dosing schedule, although effective and safe in the first study, was complicated and changed every 2 weeks. Therefore, the efficacy of a twice-weekly dosing regimen was studied as a simplified schedule in a randomized controlled trial compared with the more frequent dosing schedule. The randomized controlled trial demonstrated that 3 mg/kg administered twice weekly was as effective in preventing invasive candidiasis as the more frequent dosing schedule used in the previous study.[145] This was recently confirmed in another study.[15] Twice-weekly dosing can occur on the same two days (e.g., Tuesday and Friday) and at a specific time, thus reducing pharmacy and nursing time, preparation and administration costs, and drug cost over the prophylaxis period. Twice-weekly administration of 3 mg/kg also is associated with a decreased risk for development of azole-resistance among fungi.[150]

Manzoni and colleagues in Italy performed a multicenter, randomized, placebo-controlled trial investigating two different fluconazole doses (3 mg/kg and 6 mg/kg) compared with a placebo group.[190] In 322 infants weighing less than 1500 g, investigators reported a significant difference between the fluconazole prophylaxis groups compared with the placebo patients. Fungal colonization was significantly decreased from 29.2 percent in the placebo patients to 7.7 percent and 9.8 percent in the 3- and 6-mg/kg groups, respectively. Invasive candidiasis was decreased from 13.2 percent in the placebo patients to 7.7 percent and 9.8 percent in the 3- and 6-mg/kg groups, respectively (p = .005 and p = .02, respectively, vs. the placebo group). Fluconazole prophylaxis had similar efficacy for both the 3-mg/kg and 6-mg/kg groups. The results also showed a significant effect in infants weighing less than 1000 g as well as in infants younger than 27 weeks' gestation.

Two studies by Healy and colleagues also demonstrated that, by targeting infants weighing less than 1000 g, they were able to eliminate all *Candida*-related

*References 3, 14, 15, 24, 35, 37, 120, 121, 144, 155, 186, 190, 192, 257, 316, 327, 336.

mortality in their NICU with fluconazole prophylaxis.[120,121] In their earlier study they assessed the impact of intravenous fluconazole prophylaxis over the course of 2 years and reported that the incidence of invasive candidiasis in infants weighing less than 1000 g decreased from 7 percent (15 of 206) to 2 percent (5 of 240) (p = .01); mortality related to infection also decreased from 12 percent (4 of 33) to 0 percent (0 of 40) (p = .04). They extended the study to a 4-year period (2002-2006), and compared their results using fluconazole prophylaxis in infants during that time to results obtained in their earlier study. For all patients in their NICU, both full-term and preterm infants, the incidence of invasive candidiasis significantly decreased from 0.6 percent (19 of 3012 infants) to 0.3 percent (22 of 6393 infants) ($p < .05$). The invasive candidiasis–related mortality rate for the entire NICU also decreased from 0.1 percent to 0 percent (p = .004). The decrease in incidence of infection occurred without the emergence of fluconazole-resistant *Candida* spp. during the time of study. This demonstrates that *Candida*-related mortality for the entire NICU can be eliminated by targeting high-risk patients.

Timing of Antifungal Prophylaxis. Most studies have targeted antifungal prophylaxis to the time period when high-risk patients have additional risk factors for *Candida* infections and when these infections most commonly occur.[32] These include (1) the need for intravenous access (central or peripheral), (2) the first 4 to 6 weeks after birth, and (3) during antibiotic administration. The initial studies targeted high-risk infants weighing less than 1000 g given prophylaxis during their high-risk period of needing intravenous access, which correlates with risk factors of receiving parenteral nutrition, antibiotics, gastrointestinal diseases, or having a central venous catheter.[144] This approach also individualizes prophylaxis for infants who achieve full enteral feedings and have their central venous catheter removed early versus those who need access for a longer time period. Studies using this criteria in infants weighing less than 1000 g have had infants on prophylaxis for an average of 4 to 5 weeks.[4,18] For example, an infant of 25 weeks' gestation on full enteral feedings by 3 weeks would only need a total of six doses of fluconazole prophylaxis. Conversely, those infants needing a central venous access for 2 months would be protected for a longer time period.

Starting prophylaxis later, during prolonged antibiotic courses for more than 3 or 10 days, has been examined in retrospective studies.[196,316] The goal of these studies is to prevent invasive candidiasis but further limit drug exposure, cost, and potentially fungal resistance. These studies have demonstrated efficacy but are not as effective as prophylaxis started in the first days after birth, which also makes the approach less cost effective. Delaying antifungal prophylaxis until after colonization has been detected is 30 percent less effective than starting within 72 hours after birth.[222] Finally, in these studies the investigators reported that they only had 75 percent compliance to their protocol, so eligible patients were being missed, making them less effective from a systems standpoint.[192]

Safety of Fluconazole Prophylaxis. No significant adverse effects have been reported in randomized trials in infants treated with fluconazole prophylaxis compared with control patients. Preventing invasive candidiasis has not led to an increased incidence in other infections. The incidences of bacterial infections and NEC are similar in all studies between treatment and control groups. Fluconazole-related cholestasis has been examined closely in several studies. No cholestasis was seen between groups in the randomized controlled trials, and retrospective studies have shown by multivariate analysis that cholestasis is related to other factors such as NEC and bacterial infections and not fluconazole prophylaxis.[121,144,190,192] In addition, dosing of 3 mg/kg twice a week may be associated with less cholestasis.[3,15]

Long-term safety of fluconazole prophylaxis has also been evaluated. Neurodevelopmental status and quality of life of survivors from the first randomized controlled trial were evaluated at 8 to 10 years of life. There were no differences in the Vineland Adaptive Behavior Scales-II scores for the fluconazole-treated group compared with the placebo group. Patients scored well in the four domains: communication (95 vs. 93), daily living skills (88 vs. 87), socialization (97 vs. 94), and motor skills (92 vs. 95). Additionally, there were no differences between the two groups regarding quality of life. Survivors were happy or satisfied with school (90% vs. 100%), friendships (90% vs. 88%), and life (95% vs. 100%). Self-esteem scores were 87 versus 90. There were also no differences between groups regarding emotional difficulties or behavior problems.[151]

Azole Resistance After Neonatal Antifungal Prophylaxis

Sarvikivi and colleagues studied the use of fluconazole prophylaxis over a 12-year period in an NICU and found no *C. albicans* BSIs or resistance, no *C. glabrata* or *C. krusei* BSIs, and only two cases of fluconazole-resistant *C. parapsilosis* BSIs.[270] Additional studies of MIC have demonstrated no significant resistance among fungal strains causing colonization or infection over 5-, 6-, and 11-year time periods.[144,145,150]

Further examination of the study by Sarvikivi and colleagues demonstrated that after 10 years of targeted prophylaxis in preterm infants, the protocol was expanded to the entire NICU and the daily dose was increased to 6 to 12 mg/kg. Two infants developed a fluconazole-resistant strain of *C. parapsilosis*, and it was concluded that this single strain with decreasing susceptibility was responsible for cross infections that caused BSIs in the NICU over the entire 12-year study period. This study and others have revealed a higher risk for emergence of resistance with higher (≥6 mg/kg) and more frequent (daily) dosing of fluconazole.[270,337] This study illustrated two important points. First, it is important to use a different antifungal agent for treatment than the one used for prophylaxis so that if an infection by a resistant organism occurs, treatment will be with an effective antifungal agent. Second, although a rare occurrence, high doses and total NICU exposure to fluconazole may have led to the resistant strains. By using fluconazole for both

prophylaxis and treatment, patients were exposed to higher doses for longer periods of time. Higher doses of daily fluconazole over longer time periods are associated with resistance in adult HIV-infected patients. These mechanisms of resistance include increases in efflux pumps, point mutations, and gene overexpression.[337]

Studies of the MIC have demonstrated no significant resistance among fungal strains causing colonization or infection over 5-, 6-, and 11-year time periods in various NICUs.[121,144,145,150] These studies have also shown a relationship with frequency of dosing and fungal resistance. Twice-weekly dosing of 3 mg/kg of fluconazole prophylaxis was associated with significantly less colonization with resistant fungal isolates.[150] A retrospective evaluation of all clinical and surveillance fungal isolates obtained from infants during a 10-year period (1997-2006) revealed no significant evidence of colonization or infection with *C. glabrata* or *C. krusei* strains.[188] A comparison was made between the 6-year prophylaxis period (2001-2006) and a 4-year period before the start of fluconazole prophylaxis. The rate of *C. glabrata* or *C. krusei* colonization remained approximately 4 percent and the rate of infection was 1 percent, and no significant differences were detected when comparing the two study periods. In these studies, fungal infections were treated with AmBd preparations, which decrease the overall exposure to fluconazole and may intermittently eliminate resistant organisms.

A 2007 Cochrane review of these trials demonstrated efficacy of this treatment, with a typical relative risk of 0.23 and a number needed to treat of 9. The number needed to treat could vary substantially depending on the incidence of invasive candidiasis in NICUs.

Another systematic review investigated the effect of fluconazole prophylaxis on invasive candidiasis and analyzed all-cause mortality, *Candida*-related mortality, combined outcomes, adverse drug reactions, and fluconazole sensitivities.[147] Meta-analyses were performed using Mantel-Haenszel methods dividing the patient population into infants weighing less than 1000 g and all infants.[147] This analysis demonstrated that fluconazole prophylaxis decreased the incidence of invasive candidiasis in infants less than 1000 g by 91 percent (OR, 0.09; 95% CI, 0.04 to 0.24; p = .0004) and in all infants weighing less than 1500 g by 85 percent (OR, 0.15; 95% CI, 0.08 to 0.26; $p < .0001$). The all-cause mortality was 11 percent for the fluconazole-treated group compared with 16.3 percent for controls (OR, 0.74; 95% CI, 0.58 to 0.95; p = .017). *Candida*-related mortality was virtually eliminated (OR, 0.04; 95% CI, 0.01 to 0.31, p = .006), with prophylaxis decreasing these deaths by 96 percent.

The combined outcome of ICI plus mortality was examined from the three published randomized, controlled trials. This analysis demonstrated that 10 percent (34/319) of the fluconazole-treated infants either developed an invasive infection or died, compared with 25 percent (51/206) of placebo patients (p <.001).[143]

Nystatin

Nystatin, an enteral or orally administered nonabsorbable antifungal agent, was the first drug studied for prophylaxis in preterm infants and has been the subject of randomized, quasi-randomized clinical trials, retrospective and epidemiologic studies. These studies have added to our understanding of antifungal prophylaxis by demonstrating the benefits of prophylaxis even in NICUs with low rates of infection, confirming both a greater efficacy of prophylaxis when it is started early (by 72 hours after birth) versus later when colonization is detected and a decrease in all-cause mortality.

Sims and colleagues performed the first randomized, controlled trial of nystatin prophylaxis targeted to 67 intubated infants with birth weights less than 1250 g and demonstrated the efficacy of antifungal prophylaxis against invasive candidiasis.[283] Although the study was underpowered to detect a difference in BSI, there was a significant difference in the rate of UTI between the nystatin-treated and placebo groups (p = .01).

One important observation of antifungal prophylaxis is that starting prophylaxis after colonization is detected is not as effective as starting it shortly after birth in preventing infections. Ozturk and colleagues importantly examined the efficacy of starting antifungal prophylaxis within 72 hours after birth compared with starting it later and targeting only colonized infants once colonization was detected by surveillance cultures.[222] In their multigroup study, they demonstrated that nystatin prophylaxis was more effective in reducing *Candida* BSI when started in the first 72 hours after birth compared with identifying colonization first before instituting nystatin. They studied three groups: control patients (n = 358), colonized patients who started prophylaxis at the time colonization was detected; (n = 115), and patients who received prophylactic therapy within the first 72 hours after birth (n = 475).[223] Fungal BSI decreased by 90 percent when nystatin prophylaxis was started in the first 72 hours (47 ± 12 hours, mean ± SD) compared with only 62 percent when started after colonization was detected (12.6 ± 2.4 days). The rates of candidemia, although high in the control group, decreased significantly with oral nystatin prophylaxis in both ELBW and VLBW infants. There was no benefit for infants weighing more than 1500 g at birth.

Two large retrospective studies of nystatin prophylaxis demonstrate the use of antifungal prophylaxis even in NICUs with low *Candida* BSI rates. In the largest multicenter epidemiologic study to date (n = 14,778) comparing preterm infants who received nystatin prophylaxis with those who did not receive antifungal prophylaxis (1993-2006; Australia and New Zealand), oral nystatin prophylaxis was associated with a decrease in BSI or meningitis in infants weighing less than 1500 g (1.23% to 0.54%, $p < .0001$) and also in the infants weighing less than 1000 g (2.67% to 1.23%, $p < 0.0001$).[129] Antifungal prophylaxis was used in NICUs with a low incidence of *Candida* BSI and/or meningitis, but *Candida* UTI data are missing. The second study was performed in the United Kingdom in preterm infants of less than 33 weeks' gestational age. In addition to demonstrating efficacy, this study also found that all-cause mortality was lower in the nystatin prophylaxis group (11.8%) compared with patients not receiving prophylaxis (17.8%) (p <.0001).[101]

Study data are still sparse with the use and efficacy of nystatin prophylaxis for infants at the lower extremes of

prematurity and with gastrointestinal diseases. Limitations of the nystatin studies are that few infants of less than 25 weeks' gestation or weighing less than 750 g have been studied and nystatin may not always be able to be administered when there is an ileus, gastrointestinal disease, feeding intolerance, or hemodynamic instability.

Antifungal prophylaxis with parenteral fluconazole is effective in preventing colonization of the skin, gastrointestinal and respiratory tracts, central venous catheter and dissemination to multisite colonization, as well as eradicating colonization with *C. albicans*, the most virulent yeast for preterm infants. Aydemir and associates[14] have demonstrated that nystatin (given 0.5 mL to the oral cavity and 0.5 mL to the feeding tube every 8 hours) decreases skin, gastrointestinal, and respiratory fungal colonization.

Many questions regarding fluconazole and nystatin prophylaxis remain unanswered, but there are two studies that have compared the two strategies. One randomized controlled trial of infants of less than 1500 g birth weight compared oral fluconazole with oral nystatin prophylaxis started in the first 7 days and continued until full enteral feedings were achieved.[327] Invasive candidiasis occurred in 2 of 38 (5.3%) fluconazole-treated infants compared with 6 of 42 (14.3%) nystatin-treated infants. There were no deaths in the fluconazole-treated group compared with 7.5 percent (all-cause mortality) in the nystatin-treated group ($p = .03$). Of the six deaths, three were due to NEC, one was due to focal bowel perforation, and two were sepsis related (one *Candida*-related death). A third of the eligible patients for this study (n = 44) were excluded owing to hemodynamic instability or gastrointestinal concerns. The oral suspension of nystatin has a very high osmolarity of 3002 mOsm/L, and there is a concern with the use of hyperosmolar medications and NEC.

Aydemir and associates[14] in a three-arm randomized controlled trial of antifungal prophylaxis compared intravenous fluconazole (n = 93) and oral/enteral nystatin (n = 94) with placebo (n = 91) in infants weighing less than 1500 g. Patients were randomized (1 : 1 : 1) to fluconazole, nystatin, or placebo. This study demonstrated that nystatin prophylaxis resulted in decreased *Candida* colonization of the gastrointestinal tract, skin, and respiratory tract. Invasive candidiasis was significantly lower in both the fluconazole (3.2%) and nystatin (4.3%) groups compared with the placebo (16.5%) group (p <.0001). Although a previous study had raised concerns regarding nystatin use and NEC and all-cause mortality,[327] this study demonstrated no difference between both groups regarding NEC (fluconazole [8.6%], nystatin [9.6%], placebo [9.9%]) or mortality (fluconazole [8.6%], nystatin [8.5%], placebo [12.1%]).

Although oral fluconazole for prophylaxis was used in one of the previously mentioned studies, almost all other fluconazole prophylaxis studies have used intravenous administration in the first weeks. Although enteral fluconazole is 90 percent absorbed, absorption characteristics in preterm infants are variable and not well studied. Additionally, as discussed earlier, oral prophylaxis may not always be able to be given if patients have an ileus, NEC, intestinal perforation, or hemodynamic instability. It is during these patient conditions that fungal colonization, proliferation, and dissemination are likely to occur. For these reasons and to prevent colonization of central venous catheters, the intravenous route is recommended for fluconazole prophylaxis in preterm infants when peripheral or central intravenous catheters are present. In some studies, fluconazole was changed to enteral administration once patients achieved full enteral feedings and intravenous access was discontinued to complete 4 to 6 weeks of prophylaxis, but this may only need to be done if postnatal corticosteroid therapy is necessary.

For antifungal prophylaxis, the evidence favors fluconazole for prophylaxis owing to superior evidence, greater efficacy compared with nystatin prophylaxis (80% to 90% compared with 50% to 60%), safety in infants weighing less than 1000 g, lower costs, twice-weekly administration, and ability to be administered to all high-risk infants weighing less than 1000 g, even in the presence of gastrointestinal disease or hemodynamic instability (Table 199-3). Several studies state that nystatin is less expensive,[14,129] which is based on comparing one dose of each medication, but for a complete course of prophylaxis, because nystatin is dosed three to four times a day compared with only twice a week for fluconazole, nystatin ends up being approximately twice as expensive in the United States.

Targeted Prophylaxis in High-Risk Patients

High-risk patients should be defined as NICU patients with a significant incidence, mortality, or neurodevelopmental morbidity from their infections. Mortality and neurodevelopmental impairment are substantial in infants weighing less than 1000 g. Preterm infants in each 100-g birth-weight group less than 1000 g and by each gestational week earlier than or equal to week 27 all have invasive candidiasis rates of 5 percent or more (see Fig. 199-1). High-risk infants weighing more than 1000 g in the NICU who also have rates of 5 percent or more include those with gastrointestinal diseases, including NEC and gastroschisis, and infants weighing 1000 to 1500 g with gram-negative infections being treated with a third- or fourth-generation cephalosporin.

Infection Control and Prevention Group Recommendations

According to the Centers for Disease Control and Prevention, there are an estimated 30,000 preterm infants weighing less than 1000 g or of less than or equal to 27 weeks' gestation born each year in the United States. Instituting antifungal prophylaxis would prevent 1350 to 2700 infections, 200 to 400 *Candida*-related deaths, and 280 to 570 infants with neurodevelopmental impairment yearly. A unified, dedicated approach similar to group B streptococcus prophylaxis in all NICUs could achieve the largest impact on the prevention of invasive candidiasis. For group B streptococcus, the number needed to treat to prevent one infection is 135. Using National Nosocomial Infections Surveillance System data, the overall number needed to treat would be 13 for each *Candida* BSI prevented. Including all invasive *Candida*, bloodstream,

TABLE 199-3 **Neonatal Antifungal Prophylaxis: Fluconazole and Nystatin**

	Fluconazole	Nystatin
Effect on Colonization	CVC, skin, GI, and respiratory colonization	Skin, GI, and respiratory colonization
Level of Evidence	Level A-1 RCT data	Level A-1 RCT data
Efficacy	>90% efficacy in <1000-g infants	Efficacy 50% to 60%
Efficacy in Most Extremely Preterm Infants	Efficacy in the most extreme preterm infants (<25 wk old, <750 g)	Fewer infants <750 g or <25 wk old have been studied
Can Be Given with GI Disease or Ileus	Can be given in infants with NEC, ileus, or GI disease	May not be effective or able to be given if GI disease or ileus
Resistance	No resistance	Lack of data on resistance
Dosing	Twice-a-week dosing	Dosing three to four times a day

urine, cerebrospinal, and peritoneal infections, the number needed to treat is closer to 10 for infants weighing less than 1000 g. Owing to the severity of these infections, with 73 percent of infants less than 1000 g dying or having neurodevelopmental impairment, prevention is critical.

The *Red Book 2012* (The Report of the Committee on Infectious Diseases of the American Academy of Pediatrics) released guidelines regarding antifungal prophylaxis for preterm infants weighing less than 1000 g.[6a] This report states that: "On the basis of current data, fluconazole is the preferred agent for prophylaxis, because it has been shown to be effective and safe. Fluconazole prophylaxis is recommended for ELBW infants cared for in NICUs with ≥5% rates of invasive candidiasis. The recommended regimen for ELBW neonates is fluconazole administered intravenously during the first 48 to 72 hours after birth at a dose of 3 mg/kg, twice a week, for 4 to 6 weeks, or until intravenous access no longer is required for care. This dosage and duration of chemoprophylaxis has not been associated with emergence of fluconazole-resistant *Candida* species."

For NICUs with rates of less than 5 percent in preterm infants weighing less than 1000 g, invasive candidiasis rates should be analyzed by both gestational age and 100-g birth weight groups in those infants weighing less than 1000 g to find the break point where the rate is greater than or equal to 5 percent. Invasive candidiasis rates should be determined by including *Candida* cases caused by BSIs, UTIs, meningitis, and peritonitis over a 2- to 5-year period. It is advisable to consider gestational age as well because it has a more linear relationship compared with birth weight to both incidence and mortality. Some very extremely preterm infants may be excluded if birth weight is solely used to establish a different cutoff for prophylaxis. For example, an infant of 24 weeks' gestation can weigh between 468 and 940 g (the 3rd and 97th percentiles).[167]

NICUs transitioning to a policy of resuscitation of younger infants should use the literature to guide decision making regarding which infants should receive prophylaxis. Decisions to resuscitate and manage extremely preterm infants involve including antifungal prophylaxis in the care of these patients because prophylaxis would contribute to decreasing mortality and neurodevelopmental impairment.[315] Improving outcomes for these infants is multifactorial and needs to include all beneficial approaches as a "bundle" to have the largest effect, and antifungal prophylaxis should be included.

Targeted prophylaxis in ELBW infants to the time of intravenous access individualizes each infant to receive prophylaxis during the high-risk period based on individual risk factors. Intravenous access correlates to the time period patients have a central line, have an ileus, and are receiving antibiotics and/or parenteral nutrition. As mentioned previously, if a 26-week-gestation infant does well, achieves full enteral feedings at 3 weeks of life, and has intravenous (central or peripheral) access removed, the patient would require only 6 doses of fluconazole prophylaxis. Comparatively, if a 24-week-gestation infant takes 8 weeks to reach full enteral feedings, 16 doses of prophylaxis would be administered. If a patient needs intravenous access after a period of being on full enteral feedings, then antifungal prophylaxis would be restarted until intravenous access is no longer needed again. Targeting prophylaxis to individual patients' risk factors helps to limit drug exposure to the patient as well as fungi, which helps limit toxicity, costs, and the emergence of fungal resistance.

For NICUs with significant rates of ICI in their infants weighing 1000 to 1500 g, some retrospective studies have proposed either the presence of a central venous catheter or treatment with antibiotics for more than 3 days as guidelines for the use of antifungal prophylaxis.[35,257,316] A retrospective study by Bertini and colleagues reported that 10 percent of infants weighing 1000 to 1500 g had central venous catheters and were treated with fluconazole prophylaxis.[35] The other study targeted fluconazole prophylaxis (3 mg/kg) for 21 days to infants in whom a decision was made to give broad-spectrum antibiotics for more than 3 days. In this study,

40 percent of 1000- to 1500-g infants in their NICU were targeted for prophylaxis.[316] Data from nystatin trials and the recent multicenter fluconazole study indicate that approaches starting prophylaxis after the first week of life would be effective if fungal colonization has not already occurred.[190,222]

Fluconazole Prophylaxis Dosing Recommendations

Taking into consideration the issue of emerging antifungal resistance, a dosage of 3 mg/kg fluconazole administered parenterally twice weekly appears to be the safest and most effective schedule. This provides similar efficacy with less risk for resistance compared with higher and more frequent doses of treatment. Administering fluconazole prophylaxis (3 mg/kg) twice weekly on the same days, every Tuesday and Friday, at a specified time, also reduces pharmacy costs and may limit medication errors. This schedule continues until intravenous access is no longer required. Additionally, a different antifungal agent (e.g. amphotericin B) is selected for treatment or empirical therapy.

Infection Control Measures to Prevent Invasive Candidiasis (Table 199-4)

Prenatal Detection and Eradication of Maternal Vaginal Candidiasis. In pregnancies complicated by preterm labor or prolonged rupture of membranes, screening and treatment of vaginal candidiasis may be beneficial in preventing candidal colonization and subsequent infection in the newborn.[40,94,330]

Medication and Feeding Stewardship. Practices reducing medications that increase the risk for invasive candidiasis should be avoided if possible and instituted with stewardship, guidelines, tracking/auditing, and accountability.[153] Medications that increase risk for invasive candidiasis as discussed previously include broad-spectrum antibiotics (third- or fourth-generation cephalosporins or carbapenems), gastric acid inhibitors (H_2 blockers and proton pump inhibitors), and postnatal dexamethasone.[153] Data from a multicenter study of postnatal hydrocortisone in infants with a birth weight of less than 1000 g did not demonstrate an increase with hydrocortisone, with both treated and placebo groups having an incidence of *Candida* BSIs of 10 percent.[334] Development of starting feeding protocols (starting early and trophic and slow feed advances) and promoting breast milk feedings may aid in decreasing the risk for invasive candidiasis as well.

CLABSI Bundles. Standardized protocols for insertion and management of central venous catheters, attention to sterile practices, hub and dressing care, and closed medication delivery systems may reduce CLABSIs, including *Candida*-related BSIs.[5,57] Aly and associates reported significant reduction in all CLABSIs and elimination of *Candida* infection using a "bundled approach," which included antifungal prophylaxis in addition to line placement and maintenance interventions.[5]

TABLE 199-4 Strategies to Reduce Morbidity and Mortality of Neonatal Invasive *Candida* Infections

1. Use antifungal prophylaxis (IV fluconazole) while IV access is in use (central or peripheral) for infants with birth weight <1000 g and/or ≤27 weeks' gestational age (A-I).
   a. A-I evidence also exists for antifungal prophylaxis with nystatin but limited data are available in infants <750 g and <26 weeks' gestation. Because fluconazole prophylaxis has greater efficacy compared with nystatin, has efficacy in the most immature patients, and can be given to infants not feeding, current evidence would favor fluconazole prophylaxis in preterm infants <1000 g.
2. Start treatment of documented infections with appropriate antifungal dosing and prompt catheter removal for candidal BSI (A-II). Consider starting empirical antifungal therapy if ICI is suspected. Promptly treat congenital cutaneous candidiasis.
3. Decrease broad-spectrum antibiotic use (B-II). Restrict third- and fourth-generation cephalosporins and carbapenems to treatment of proven gram-negative infections. Add antifungal prophylaxis while patient is receiving these agents.
4. Decrease H2 blocker and proton-pump inhibitor use (B-II). Use only for proven gastritis, and restrict use to 3 days or until symptoms resolved.
5. Decrease postnatal dexamethasone use (B-II). Use only for severe lung disease.
6. Institute central line–associated bloodstream infection reduction bundles (B-II).
7. Monitor rates of ICI, including BSI, UTI, meningitis and peritonitis infections and feedback to staff (B-II).

Level of evidence from U.S. Public Health Service Grading System for ranking recommendations in clinical guidelines. Strength of recommendation and levels of evidence: A, good evidence; B, moderate evidence; C, poor evidence: I, at least one randomized clinical trial; II, at least one well-designed but nonrandomized trial; III, expert opinions based on experience or limited clinical reports.

BSI, bloodstream infection; IV, intravenous; ICI, invasive *Candida* infection; UTI, urinary tract infection.

Lactoferrin

In a randomized controlled trial of bovine lactoferrin (bLF) in infants with a birth weight of less than 1500 g the incidence of late-onset sepsis was significantly lower in the bLF and bLF-plus probiotics groups than in the placebo patients.[189] Subanalysis found that invasive fungal infections were also significantly less common with lactoferrin alone compared with placebo. One limitation of the study was that there were only 9 to 18 infants weighing less than or equal to 750 g in each group. Confirmation of the findings in extremely preterm infants is needed.

Outcomes

For preterm infants, invasive *Candida* infections are associated with high mortality and neurodevelopmental impairment.

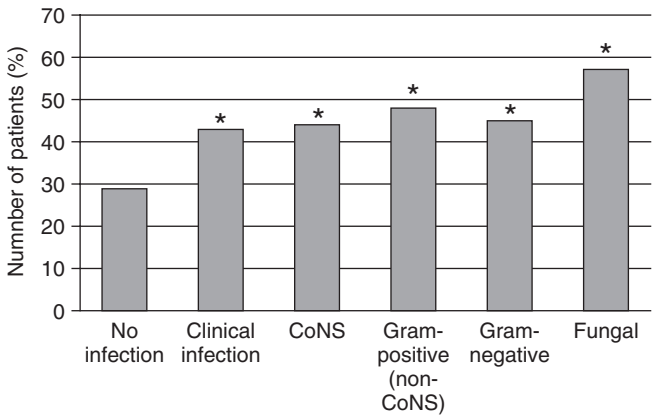

FIGURE 199-5 ■ Neurodevelopmental impairment and bloodstream infection in infants weighing less than 1000 grams. *$p \leq .001$ compared to no infection group. Neurodevelopmental impairment was determined by one or more of the following: Bayley Infants Score of Development physical or mental developmental index less than 70, cerebral palsy, or visual or hearing impairment. Clinical infection was defined as late-onset infection with negative cultures with antibiotic treatment for 5 or more days. CoNS, coagulase-negative staphylococci.

Neurodevelopmental Impairment

Invasive candidiasis may lead to significant neurodevelopmental impairment even in absence of documented fungal meningitis. Neurodevelopmental impairment in most studies is the presence of one or more of the following: low mental and motor development using Bayley Scales of Infant Development II, cerebral palsy, deafness, and/or blindness. With the use of these criteria, the incidence of neurodevelopmental impairment is 57 percent in infected infants versus 29 percent in noninfected ELBW infants (Fig. 199-5).[32,298] The incidence was similar for cases of *Candida* meningitis at 53 percent. These data also are similar to a study from an earlier time period.[98] Neurodevelopment was intact in 41 percent of *Candida*-infected patients and 65 percent of controls ($p = .02$). Periventricular leukomalacia was not significantly different between groups ($p = .06$). In this study, neurodevelopmental outcome was related to timing of initiation of antifungal therapy. Commencement of antifungal therapy was 5.1 ± 3.0 days after blood culture was drawn in those infants who had severe disabilities or died compared with 2.1 ± 1.3 days in those who had normal or mildly impaired outcomes ($p < .0001$).

Survival

Mortality is high with invasive *Candida* infections in ELBW infants. A recent multicenter study of infants weighing less than 1000 g at birth found that overall mortality was 34 percent for infants with invasive candidiasis compared with 14 percent in those without invasive candidiasis. [33] All-cause mortality rates were 28 percent for *Candida* BSI, 26 percent for *Candida* UTI, and 50 percent for other sterile sites (meningitis and peritonitis); and if two or more culture sites were involved (BSI +UTI or UTI + meningitis), the mortality rate was 57 percent.

There is a marked difference in overall and attributable mortality between infants weighing less than 1000 g and larger, more mature infants with invasive candidiasis. In infants weighing less than 1000 g with invasive candidiasis, a recent analysis reported an all-cause mortality rate of 26 percent compared with 13 percent in infants without candidiasis. For infants of more than 1000 g with invasive candidiasis versus those without, mortality was 2 percent compared with 0.4 percent.[347]

Candida*-Related Mortality*

Identifying *Candida*-related mortality is difficult and may include attributable mortality, death within a specified number of days from onset of infection (3, 7, 14, or 30 days), or review of each death using predetermined definitions. In infants weighing less than 1000 g with invasive candidiasis, these rates may range from an attributable mortality from epidemiology studies[33,347] of 13 to 15 percent to 23 to 66 percent when examining deaths of patients in the placebo or control groups in the prophylaxis studies.[149] Mortality increases at the lower ages of gestation of less than 26 weeks, and different mortality rates, similar to infection rates, will be influenced by resuscitation and admission rates of these extremely preterm infants.[135]

CHAPTER 200

Coccidioidomycosis

Ziad M. Shehab • Kareem W. Shehab

Coccidioidomycosis is an infection caused by a dimorphic fungus of the genus *Coccidioides*. The primary pulmonary infection produced by this organism usually is self-limited, but disseminated and fatal disease may occur. In the United States, coccidioidomycosis is an endemic disease of the southwestern states and results in 150,000 infections per year.[68] In other parts of the United States, it also is seen in individuals who have traveled to or lived in the endemic areas of the Southwest or Mexico.[25,32,50] The disease is endemic in other areas of the Western Hemisphere, most notably in northern Mexico and in certain countries in South and Central America.[113] Pulmonary disease is underrecognized even in areas of high endemicity.[96,148] With population growth in the endemic areas of the Southwest and increased population mobility, clinicians in nonendemic areas are likely to encounter this disease, particularly in its more severe or disseminated forms. Reactivation, especially in the immunocompromised host, can result in disease long after primary infection, thus emphasizing the need for a thorough travel history.

Coccidioidal granuloma, a form of disseminated coccidioidomycosis, was described first by Posadas in 1892 in Argentina. The disease initially was thought to be a form of skin tumor. Rixford and Gilchrist associated it with what they thought was a protozoon resembling coccidia and named it *Coccidioides*. Ophüls and Moffitt, in 1900, were the first to attribute coccidioidal granuloma to the fungus *Coccidioides immitis*. Although earlier investigators had noted fungal growth on cultures from pathologic specimens, these were dismissed as contaminants. Between 1900 and 1936, numerous reports of coccidioidal granuloma appeared in the medical literature, but the association between coccidioidal granuloma and acute pulmonary infection remained unrecognized. In 1936, Gifford[73] and Dickson were the first to describe that *C. immitis* is the causative agent of what had previously been known in California as San Joaquin fever or valley fever.[66]

In the period that followed, the epidemiology of the disease[132,135] and ecology of the organism[57,104] were studied carefully by many investigators, led by the efforts of Charles Smith. Many different forms of therapy were tried for disseminated disease during this era, but none proved satisfactory.[61] In 1957, with the use of amphotericin B, effective antifungal therapy became available, and the prognosis associated with the disseminated form of the disease improved.

As with many pathogenic fungi, the life cycle of *C. immitis* demonstrates two distinct phases: a saprophytic, or vegetative, phase and a parasitic phase. In nature and on most laboratory media, the organism grows as mycelia with branching, septate hyphae. After 5 to 7 days, the aerial mycelia show development of rectangular spores (arthrospores, arthroconidia) separated by empty nonviable cells (Fig. 200-1). At this stage, the hyphae become fragile, and the arthroconidia easily become airborne. Their size, measuring 2 to 8 μm in diameter, allows them to reach the alveolar spaces of the lung when they are inhaled.

On gaining access to mammalian host tissues, the arthroconidia begin the parasitic phase of their life cycle. They enlarge and develop into spherules during the course of approximately 48 hours while undergoing internal segmentation to form endospores that are 2 to 5 μm in size. The spherules (Fig. 200-2) are round, double-walled structures measuring 20 to 100 μm in diameter. Endospores are released into the surrounding tissues by rupture of the spherule wall, where they mature

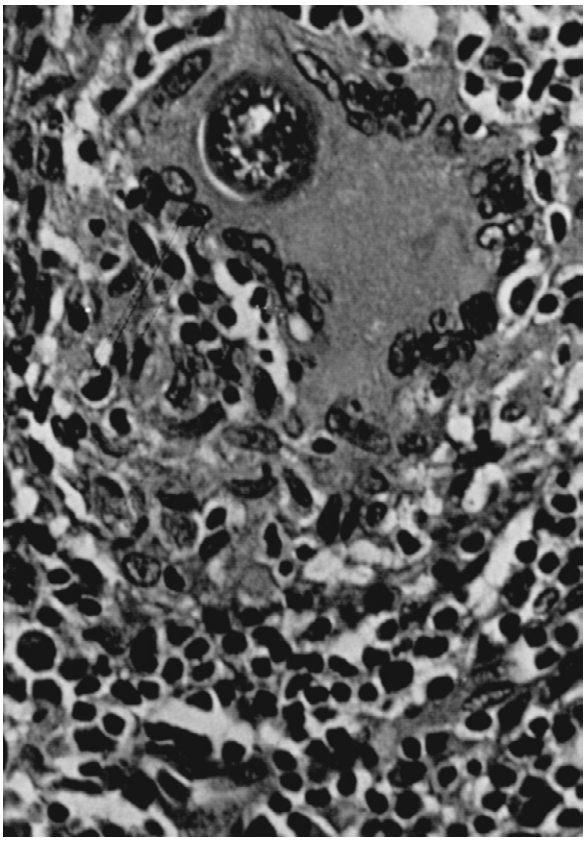

FIGURE 200-2 ■ Coccidioidal granuloma showing a multinucleated giant cell containing a spherule filled with endospores. The adjacent field contains lymphocytes and plasma cells.

into more spherules, repeating the tissue phase of the life cycle.[126]

Coccidioides spp. grow on laboratory media relatively easily, producing colonies that become visible in 3 to 4 days. They represent the mycelial phase of the fungus and appear as flat, smooth, and gray colonies from which spicules may project in some, whereas others have a velvety, membranous appearance. Colonies appear as tufts in the second week and then develop cobweb-like aerial hyphae. Pigmentation may be seen after 2 weeks and is observed best as a brownish undersurface. Variability in colony morphology can be significant. Of the two species of *Coccidioides*, *C. immitis* is prevalent in California; *C. posadasii* accounts for isolates from Arizona, Texas, Mexico, and parts of Central and South America.[62] No clinical differences have been recognized between the two species. Identification is accomplished by inoculation of the mycelia into laboratory animals and demonstration of the conversion of the fungus to the spherule phase. However, reliable techniques showing in vitro conversion to the spherule stage, demonstration of specific exoantigens, or identification of the organism by genetic probes have been developed and obviate the need for animal inoculation.[126]

EPIDEMIOLOGY

Coccidioidomycosis is endemic in the Western Hemisphere between 40 degrees of latitude north and south. In the United States, these areas lie in the southwestern states, especially in Arizona, California, western Texas, and southern New Mexico. The areas in which coccidioidomycosis is prevalent generally correspond to the lower Sonoran life zone.[113] This life zone is characterized by an arid to semiarid climate, with hot summers and relatively short winters with limited rainfall and few freezes. Most of the fungal growth occurs during the rainy season in alkaline soil and at low altitude. The fungus is found in the soil to a depth of 20 cm, especially in the walls of rodent burrows. Environmental conditions in endemic regions apparently inhibit growth of competitive organisms.[57,62] A variety of animals, including rodents, cattle, sheep, and dogs, have been shown to develop naturally acquired infection. Arthroconidia become airborne during wind storms or during disruption of soil by construction work and farming.[31,63] Prolonged droughts followed by heavy rains also have resulted in an increase in the number of cases, as occurred in California in 1992 and 1993.[30] Archeological excavations and digging by children in soil containing the organism have resulted in local outbreaks.[33,160] In addition, transmission has been reported to occur by contaminated fomites, such as dusty clothing and farm products.[1,124] The ease with which arthroconidia become airborne makes the organism dangerous to laboratory personnel. Epidemics have resulted from inadvertent opening of a single culture plate.[90] Guidelines for management of accidental laboratory exposures have been published.[140]

Primary coccidioidal infection occurs most frequently in summer and fall, after the rainy seasons. Arthroconidia are more likely to become dispersed during dry weather

after promotion of greater hyphal growth by a wet environment.[57,132,133] Variations in seasonal incidence are partially explained by the occurrence of dust storms[113,133] and earthquake activity.[31] Significant increases in the number of cases are being seen in the Southwest; high incidence periods in the winter are associated with environmental and climactic changes, such as construction activity and prolonged dry periods.[67,115]

Susceptibility to primary coccidioidal infection is unaffected by age, sex, or racial background.[61] Estimates of infection rates in endemic areas, which are based on the risk for development of infection in children, had declined as urbanization developed with dust abatement and paved roads. For example, infection rates measured by skin test reactivity to skin test antigens declined from approximately 10 percent in 1937-1939 to 2 percent in 1959 and to less than 1 percent thereafter in kindergarten and first-grade students who had lived all of their 5 to 7 years in Kern County, California.[100] Similarly, the annual risk has been estimated to be 2 and 4 percent in college students in Tucson, Arizona.[95] Incidence rates are higher in older male children, in rural areas, during wind storms, and for those with occupational exposure.[120,122,132] Significant increases in the number of reported cases have been observed in Arizona and California recently.[81] In contrast with susceptibility to primary infection, the frequency of dissemination and severe disease varies considerably, being higher in infants,[38,39,87,132] Filipinos, Hispanics, and blacks.* Immunosuppressed hosts also are at increased risk for development of disseminated infection. Persons receiving anti–tumor necrosis factor (TNF) alpha therapy are at increased risk for severe coccidioidomycosis.[13] In the era of potent antiretroviral therapy, the severity of the disease has decreased among human immunodeficiency virus (HIV)–infected individuals and is inversely associated with control of the infection.[107]

The tissue phase of the organism is the spherule, which is not infectious. Although mycelial growth can be found in cavities when they are carefully searched, no evidence exists of person-to-person spread of *C. immitis*,[78,159] except in special situations in which the fungus is allowed to revert to its airborne form, such as growth from wound drainage on a plaster cast.[56] Patients with coccidioidomycosis do not require isolation, even when draining wounds are present. In such circumstances, dressings should be changed frequently to prevent growth of the fungus and the formation of arthroconidia.

Once limited to the lower Sonoran life zone, the disease is seen throughout the country because of the ease and frequency of travel, increased populations in endemic areas, and reactivation of infection in immunocompromised hosts, including transplant recipients, patients with acquired immunodeficiency syndrome (AIDS), and recipients of TNF-α inhibitors. In these patients, delays in establishing the diagnosis can be fatal, and rapid recognition of the diagnosis and prompt institution of appropriate therapy mandate that a timely and accurate diagnosis be established.

*References 46, 63, 73, 81, 83, 123.

PATHOGENESIS AND PATHOLOGY

Acquisition of *Coccidioides* spp. infection usually is through the respiratory tract. It is surmised that most human infections result from exposure to only a single spore.[68] Growth of the organism stimulates an intense inflammatory response, and in most patients the infection remains localized to the lung and hilar nodes. In a minority of patients, clinically significant extrapulmonary dissemination occurs by way of lymphatics or the bloodstream. Rarely, direct cutaneous inoculation may occur by puncture of the skin with a contaminated object.[34,110]

The initial inflammatory response of acute pulmonary coccidioidomycosis predominantly is a polymorphonuclear leukocyte reaction, possibly related to a chemotactic effect of endospores or complement activation from other *Coccidioides* antigens. Tissue necrosis, spherules, and a few mononuclear cells are present at this stage of the disease, but epithelial giant cells are infrequently seen. This bronchopneumonic process can occur in any lobe of the lung. Although this response may slow the progress of the infection temporarily, it ultimately cannot arrest the disease process,[68] as neutrophils do not show any killing of coccidioidal forms. Killing has been demonstrated with natural killer cells and mononuclear leukocytes. Numerous studies have demonstrated the importance of T cell–mediated responses, particularly the Th1 response, in controlling the infection, as evidenced by delayed cutaneous hypersensitivity, peripheral lymphocyte transformation, and production of interleukin-12, interferon-γ, and TNF-α.[68] Dermal hypersensitivity correlates well with other measures of peripheral blood lymphocyte responsiveness, such as lymphocyte transformation and cytokine production.[2] In patients with progressive disease, cell-mediated immune defenses become defective, possibly because of defective antigen presentation, antigen overload, suppressor cells, immune complexes, or fungal immunomodulatory substances, resulting in an undesirable and ineffective Th2 response.[44]

Disseminated coccidioidomycosis resembles progressive tuberculosis of childhood, which usually occurs within weeks or months after the initial infection develops. However, endogenous reactivation may also occur, particularly among individuals with immunosuppressive conditions.[2,20,67] Extrapulmonary spread may occur anywhere in the body, but lesions are found most frequently in bone, soft tissue, lymph nodes, liver, spleen, and meninges. Bone lesions resemble chronic osteomyelitis (Fig. 200-3). Infection of the brain parenchyma is a rare event, but meningitis occurs commonly and frequently localizes to the basilar area.[21,83]

The pathologic findings of fatal coccidioidomycosis have been reviewed extensively.[84] The tissue reaction in disseminated disease predominantly is granulomatous but can be accompanied by elements of acute inflammation. Typically, the granulomatous lesions contain abundant giant cells and histiocytes. Caseous necrosis is a common occurrence, and spherules usually can be identified lying freely and within macrophages (Fig. 200-2). Fibrous tissue may surround areas of inflammation, but calcification is an infrequent occurrence.

FIGURE 200-3 ■ Osteomyelitis in a 14-year-old boy with disseminated coccidioidomycosis. An osteolytic lesion involves the distal radius.

Most cases of disseminated coccidioidal infection in the first months of life have been associated with heavy exposure to dust; these infants apparently acquire their infection by the respiratory route.[40,87] Nearly all the described infants in this age group have had severe disease,[38,39,87,145] but primary infection sometimes may go unrecognized.[39] Although women who develop coccidioidomycosis late in pregnancy may be at increased risk for development of disseminated disease,[154] with a few exceptions,[36,101] their infants are born free of infection.[40,41,131,149] In several patients with apparent perinatal transmission, the mothers had coccidioidal endometritis, and infected amniotic fluid was the most likely source of their infants' infections.[14,101,127,138]

Dissemination of coccidioidomycosis occurs more frequently in immunosuppressed patients who have resided in an endemic area,[67,105] but immunologic abnormalities have not been detected in other groups, such as Filipinos, who also are at high risk for development of disseminated disease. Once dissemination occurs, the patient's cell-mediated immunity is frequently impaired,[2,28,43,44,137] especially if extensive infection is present.[10,135] Dissemination can occur in patients who have a selective lack of response to coccidioidal antigens, as evidenced by negative skin test results to coccidioidin or spherulin, and who do not have evidence of generalized anergy. In vitro measurements of lymphocyte transformation to phytohemagglutinin or to specific cell wall antigens of *C. immitis* are also depressed.[10,43] In contrast, patients with disseminated disease with positive skin test results usually have normal in vitro lymphocyte responses that are similar to those found in healthy persons who have recovered from primary infection.[44,111,162] Furthermore, patients who have recovered from severe disseminated disease may show return of specific and nonspecific cell-mediated immunity.[10,28,61,137] Infected children demonstrate immunologic findings similar to those described in adults, but they have not been studied as extensively.

CLINICAL MANIFESTATIONS

Primary Infection

The clinical features of acute coccidioidomycosis in children are thought to be similar to the manifestations observed in adults.[134] Studies in Air Force personnel indicate that infection is subclinical or indistinguishable from a mild upper respiratory tract infection in 60 percent of infected persons.[135,137] Twenty-five percent experience an influenza-like illness lasting 1 to 2 days, whereas the remainder have more severe lower respiratory illnesses including lobar pneumonia, pleural effusions, and, occasionally, pericarditis.[61,68,116] With intensive exposure, such as occurs during military field exercises, the attack rate may be high and a large proportion of infections may be symptomatic.[46] The disease may mimic bacterial pneumonia and sepsis.[6,103] When serologic studies are used routinely in the evaluation of adults with community-acquired pneumonia in endemic areas, 17 to 28 percent of cases are the result of coccidioidal infection.[96,148] However, only 2 to 13 percent of adults with community-acquired pneumonia are tested for coccidioidomycosis, even in highly endemic areas.[35] The most common form of symptomatic infection is a subacute, self-limited pulmonary illness. Some patients, however, will experience more complicated pulmonary infections or even extrapulmonary disease. Outside of endemic areas, such patients are most likely to be encountered by physicians and may undergo extensive workups, and delays in establishing the diagnosis may occur if coccidioidomycosis is not considered.[24,25,50] Severe disease is more likely to develop in individuals with diabetes or those with a recent history of cigarette use.[123]

The usual incubation period is 10 to 16 days, but it may range from less than a week to almost a month.[61] In young adults, fatigue (77%), cough (64%), chest pain (53%), and dyspnea (17%) are the most common symptoms. Fever is present in 46 percent, with arthralgias, myalgias, and headaches each reported in 22 percent.[144] Chest pain sometimes is severe and is usually pleuritic.[144] It may be followed by vague chest pain that persists for several months.[68] In infants, stridor rarely may be present as a result of primary infection of subglottic tissue.[72,79]

Transient rashes probably occur more frequently in children than in adults and are observed in slightly more than half of symptomatic children[52,82,120]; the rash is manifested as erythema nodosum, erythema multiforme, toxic erythema, Sweet syndrome, and reactive interstitial granulomatous dermatitis. Erythema nodosum is the most characteristic lesion, usually appears 1 to 3 weeks after the onset of illness, and is associated with a lower risk

of disseminated disease.[9,52,82,61,132] Erythema multiforme–like lesions are common in children, as is toxic erythema, a macular, papular, urticarial, or morbilliform rash that is manifested within 48 hours of onset of symptoms. It may last for several weeks and is followed sometimes by palmar desquamation.[52] Rarely, primary cutaneous coccidioidomycosis is seen and results from cutaneous injury and direct inoculation of the skin. Lesions develop 1 to 3 weeks after an injury and are often associated with localized lymphadenitis. In adults, only mild constitutional symptoms are usually present, and the process spontaneously resolves within 2 to 3 months. However, in children, progressive and prolonged infection commonly occurs; antifungal therapy may be necessary.[110,158] Transmission by cat bite has been reported.[65]

Acute arthritis or arthralgia may accompany primary coccidioidal infection. These findings usually are transient, do not signify dissemination, and are thought to represent a hypersensitivity reaction.[54]

The radiographic appearance of primary coccidioidomycosis is nonspecific.[11,37,77,120] Bronchopneumonic infiltrates are the most frequent finding and often are associated with hilar lymphadenopathy. Segmental or lobar consolidation and nodular or patchy pulmonary infiltrates also can occur. Small pleural effusions or pleuropericardial reactions also occur in 15 percent of hospitalized patients (Fig. 200-4) and are usually sterile.[102,108] These radiographic findings resolve in 90 to 95 percent of symptomatic cases, albeit slowly in some, and usually do not necessitate specific therapy.

In neonates, the constellation of radiographic findings of focal consolidation with diffuse nodular densities associated with nonspecific symptoms and minimal clinical evidence of respiratory tract infection has been described but is not specific for coccidioidomycosis.[14,37] Chorioretinitis as a manifestation of systemic disease also has been reported.[74]

In a minority of patients, cavitation, nodule formation, bronchiectasis, or calcification may develop at the site of the pulmonic infiltrate.[16] The cavities usually are asymptomatic and rarely require surgical therapy. Nodules and thin-walled cavities develop in 5 percent of patients with coccidioidal pneumonia. These lesions are well circumscribed, typically single, and less than 6 cm in diameter. Many resolve spontaneously but result nonetheless in the need for prolonged care and convalescence. Rarely, the cavities lead to pneumothorax, empyema, or bronchopleural fistula, which is more likely to occur in immunosuppressed patients or in diabetics.[88] In adults, nodules may be confused with carcinoma of the lung, thus requiring excision or diagnostic fine-needle aspiration.[53] A miliary pattern, indicating hematogenous or lymphatic spread, sometimes can be appreciated in immunocompromised hosts and rarely in immunocompetent hosts.[8] On occasion, endotracheal or endobronchial lesions can be demonstrated by endoscopy.[117]

The manifestations of primary coccidioidal disease thus are varied, and no constellation of symptoms and signs is specific enough to establish a diagnosis, rendering the use of specific laboratory tests a requirement.

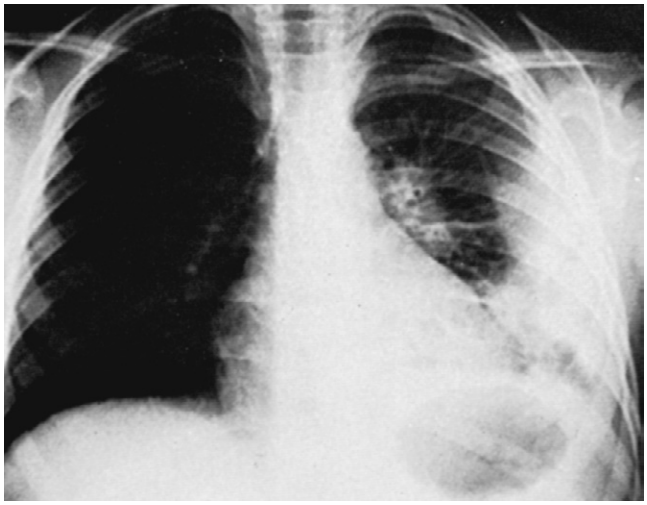

FIGURE 200-4 ■ Chest radiograph of a patient with acute pulmonary coccidioidomycosis showing pulmonary infiltrates, extensive pleural fluid, and enlargement of the left hilum.

Disseminated Coccidioidomycosis

Except in very young children, dissemination appears to occur less frequently in pediatric patients than in adults (0.5%), although this view has been questioned.[92,130] Spread of infection usually becomes apparent within a few weeks to a few months after the initial infection occurs and is heralded by persistent fever, toxicity, and insidious development of lesions outside the chest. An occasional patient develops disseminated disease after having an asymptomatic primary infection.[48,60,92] Disseminated disease rarely can be manifested with peritonitis, pericarditis, empyema, laryngeal lesions, or neck or gluteal abscesses.[22,47]

Skin Disease

The most common cutaneous manifestation of disseminated coccidioidomycosis is a verrucous granuloma that is characteristically located at the nasolabial fold.[61,82] These lesions may heal or may continue to progress. They can also take the form of papules, nodules, subcutaneous abscesses, pustules, or sinus tracks; they may be single or multiple and may ulcerate. Rarely they appear similar to mycosis fungoides. Cutaneous lesions result from blood-borne dissemination and contain the organism. These lesions mimic those caused by other fungi, tuberculosis, actinomycetes, and syphilis.[52]

Bone and Joint Disease

Involvement of bone results in chronic osteomyelitis,[17,49,89] which may drain into soft tissue (Fig. 200-5) and form fistulas to the overlying skin.[48] The bones most frequently infected are the vertebrae, tibias, metatarsals, skull, and metacarpals. The lesions are present in a single bone in 60 percent of cases; two bones are involved in 20 percent, three in another 10 percent, and four or more bones in the remainder. On radiographic examination, the lesions typically are lytic (Fig. 200-3). Involvement of the axial skeleton is common. Vertebral osteomyelitis is

FIGURE 200-5 ■ Swelling and chronic draining sinus over the proximal phalanx of the index finger. The infant has disseminated coccidioidomycosis with involvement of the underlying bone.

characterized by involvement of all parts of the vertebra with relative sparing of the disk, in contrast to tuberculosis. Skull involvement typically leads to erosion of the outer table. Spread of infection locally leading to meningitis is a serious concern with vertebral osteomyelitis. Arthritis has a waxing and waning course and usually involves the knee or ankle. It may also result from direct inoculation of the joint, such as with a cactus spine.

Meningitis

Meningitis may be the sole site of extrapulmonary disease, particularly in whites, but it also occurs as part of widespread dissemination.[21,91,128] It may be manifested acutely with the primary infection or appear up to 6 months later. The most common symptom is headache. Altered mental status, sluggishness, ataxia, and vomiting are other common symptoms. Children often lack signs of meningeal irritation and sometimes present with focal neurologic deficits. The pathologic process is that of granulomatous and suppurative basilar meningitis, with frequent presence of parenchymal involvement with granulomas and abscesses of the spinal cord and brain.[59,109] Vasculitic complications with infarction and stroke-like findings may be abrupt in onset.[59,157] Hydrocephalus is commonly present in children and is treated by placement of a ventriculoperitoneal shunt.[128] Before amphotericin B became available, coccidioidal meningitis was uniformly fatal, and the average length of survival in children was 5.5 months. Death with coccidioidal meningitis now is a relatively rare event. However, adults with neuroimaging abnormalities, especially hydrocephalus with or without cerebral infarction, have a high mortality rate.[7]

Examination of the cerebrospinal fluid (CSF) usually reveals moderate pleocytosis, usually between 100 and 500 white blood cells/mm^3 (with a range of a few to more than 10,000 white blood cells/mm^3) with mononuclear cell predominance, hypoglycorrhachia, and elevated protein level.[94,128] A polymorphonuclear cell predominance may be present early in the course of the illness. These findings are typical for CSF sampled from the lumbosacral space. However, considerable variation occurs in the cell count, chemistry, and antibody content of fluid obtained from the ventricles, cisterna magna, or lumbosacral space.[75,80,128] The lumbosacral space exhibits the most severe changes, that is, lower glucose concentration, higher protein level, higher cell count, and higher CSF coccidioidal complement fixation titer. Eosinophilic pleocytosis in the CSF is suggestive of coccidioidal meningitis and should prompt an appropriate diagnostic workup; it is of no prognostic value.[119] The CSF culture often is negative for the fungus, whereas CSF antibody is detectable in up to 95 percent of patients.[94] The diagnosis is confirmed by a positive CSF culture or serology and is supported by a positive serum serologic result or culture of *Coccidioides* spp. from a nonpulmonary site.

Coccidioidomycosis in Pregnancy

Like tuberculosis, coccidioidomycosis can involve the pelvic organs. Early studies had indicated an alarming risk of dissemination and death in women who acquired coccidioidomycosis, especially during the third trimester of pregnancy. In a population-based study, Wack and colleagues[154] showed that coccidioidomycosis occurs infrequently during pregnancy but remains associated with serious complications when the disease develops in the third trimester or soon after delivery. This is thought to be the result of immunosuppression and increased hormonal levels that favor the growth of spherules.[139] Pregnant women with erythema nodosum are much less likely to experience disseminated disease than are those without.[9] Wide variations are reported in the rates of dissemination and fatality among pregnant women, although all studies agree that the rate of dissemination in pregnant women is higher than that in the general population.[26,45] Maternal infection is more severe when it is acquired late in pregnancy and most severe in the immediate postpartum period.[12]

Coccidioidomycosis in the Immunocompromised Host

Control of coccidioidal infection depends primarily on cell-mediated immunity. Conditions that result in immune suppression, particularly T-lymphocyte dysfunction, such as those present in patients with lymphoma or bone marrow or solid-organ transplantation, predispose the individual to more fulminant forms of coccidioidomycosis.[20,121] Infections may be primary or the result of reactivation. Solid-organ transplant recipients are at the highest risk in the first year after undergoing transplantation, especially during primary infection. Dissemination also can occur late as a result of reactivation of a prior infection. The risk is increased by a prior history of coccidioidomycosis or a positive serologic reaction just before transplantation.[20] By use of targeted prophylaxis with fluconazole, however, the overall rate of coccidioidomycosis after liver transplantation (2.4%),

renal transplantation (3%), and hematopoietic stem cell transplantation (1.5%) can significantly be reduced.[23,153]

An increased risk of acquiring severe symptomatic disease was described in patients receiving TNF-α antagonists.[13] In patients infected with HIV, the severity of pulmonary disease is related inversely to virologic control, with greatly increased risk for development of severe pulmonary and extrapulmonary disease when the CD4 count is less than 250 cells/μL. The morbidity in HIV-1–infected patients receiving antiretroviral therapy and with CD4 counts of 250 cells/μL or higher is now similar to that in non–HIV-infected persons.[3,107] In endemic areas, the risk for coccidioidomycosis in solid-organ transplant recipients is 4 to 9 percent.[20,150,153] Most occurs in the first year after solid-organ transplantation. One third of such patients will have disseminated disease, with a mortality rate of 13 percent among those with posttransplantation coccidioidomycosis.[153] Genetic factors, such as deficiencies in interferon-γ receptor 1 or in interleukin-12 receptor β1, are being recognized in some patients with refractory disseminated coccidioidomycosis.[151,152]

DIAGNOSIS

In endemic areas where an awareness of the disease exists, the diagnosis of coccidioidomycosis usually is established readily by obtaining appropriate laboratory studies. However, even in these areas, coccidioidal pneumonia may be more prevalent than previously thought and may be underdiagnosed.[96,148] In nonendemic areas, the diagnosis is often not considered unless a travel history is obtained. Cases have occurred even after brief exposure in an endemic area. Primary pulmonary coccidioidomycosis resembles other lower respiratory illnesses, including those caused by viruses, bacteria, mycoplasma, *Mycobacterium tuberculosis*, and other fungi (e.g., *Histoplasma*).

The hematologic findings in primary coccidioidal infection consist of elevation of the erythrocyte sedimentation rate, leukocytosis, and, frequently, eosinophilia.[61] Specific diagnosis usually is based on the results of serologic reactions, cultures, sputum examination, and histologic examination of tissue.

Culture and Identification of the Fungus

The organism is detected readily by direct examination and culture from purulent material. The yield from other sources, such as pleural fluid, blood, and gastric aspirates, is somewhat lower. Only approximately one third of CSF samples are culture positive, and direct examination of the CSF almost always yields negative results.[82,144] Detection of the fungus from the blood is an uncommon occurrence and is associated with severe forms of disseminated disease.[4] Tissue biopsies of pleura, synovium, or meninges often yield the organism by culture or by histologic demonstration of coccidioidal spherules.

In severe pulmonary or disseminated disease, microscopic examination of bronchoalveolar lavage specimens, exudates, or biopsy specimens is diagnostic if typical spherules containing endospores are seen. Hematoxylin and eosin–stained sections can be used to demonstrate spherules, but they are used mainly to show the inflammatory process. The periodic acid–Schiff stain is useful for demonstration of spherule contents (Fig. 200-6), whereas methenamine silver stains highlight the wall of the spherule. Potassium hydroxide stains are useful but lack sensitivity and specificity; calcofluor white fluorescent stains are more sensitive but require experienced technologists.[126] Cytologic examination of sputa is more sensitive than are potassium hydroxide stains.[155] Cytologic examination of bronchial wash or bronchoalveolar fluid is diagnostic in only approximately one third of persons with or without HIV infection and is less sensitive than culture.[53] The Gram stain is not useful as it is not picked up by the spherules.

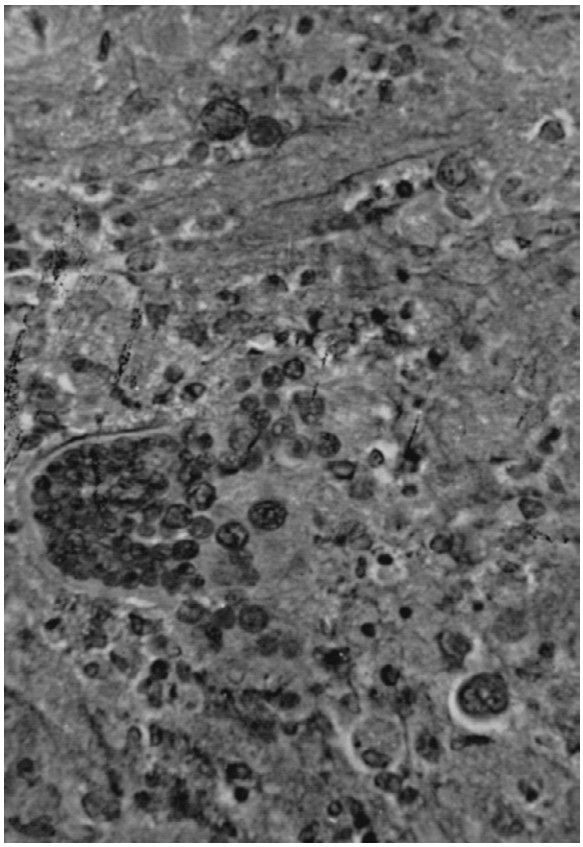

FIGURE 200-6 ■ A spherule that recently has ruptured and is in the process of releasing endospores.

With the rare exception of persons with primary cutaneous infection, the finding of spherules in tissues outside the thoracic cavity is evidence that the patient has disseminated disease. For this reason, biopsy may be useful to establish a diagnosis, particularly in patients with negative or low complement fixation antibody titers. Cultures of *Coccidioides* spp. from body fluids, sputum, or exudates can be performed on most laboratory media. If coccidioidomycosis is suspected, the use of mycologic media containing cycloheximide can be helpful.[90,142] The handling of the cultures is hazardous and requires special biosafety level 3 practices. *Coccidioides* spp. are no longer designated Select Agents by the Centers for Disease

Control and Prevention, *Coccidioides* spp. grow on routine bacterial, fungal, and *Legionella* media. Once a nonpigmented mold is grown, confirmation is achieved best by use of genus-specific genetic probes that allow rapid confirmation, usually within hours.[112] The probe does not differentiate between *C. immitis* and *C. posadasii*, and it is not clinically relevant to differentiate the two species. Real-time polymerase chain reaction assays are being developed for rapid detection of *Coccidioides* spp. in clinical specimens but are not commercially available.[15]

Skin Test

Intradermal skin tests using lysates of either the mycelial phase (coccidioidin) or the spherule phase (spherulin) have been used to elicit delayed hypersensitivity. They have primarily been used as epidemiologic tools and are no longer commercially available. Skin test reactions may be negative in immunocompromised individuals and in persons with disseminated disease.

Serologic Studies

The initial antibody response to coccidioidal infection predominantly is in the IgM fraction and is responsible for the positive precipitin test result that accompanies primary infection. Fifty percent of patients yield positive results in the first week, and 90 percent show precipitins within 2 to 3 weeks. Thereafter, antibody reversion occurs, and by 5 months, only 10 percent of patients with uncomplicated infection yield positive results.[136] These IgM responses can be measured by tube precipitins, latex agglutination, enzyme immunoassay, or immunodiffusion methods.[114] Precipitating IgM antibody detected by the tube precipitin assay or by immunodiffusion usually indicates acute infection.[136] Latex agglutination is sensitive, rapid, and easy to perform but frequently yields false-positive reactions[114]; positive results should be confirmed by a second method. Latex agglutination results in false-positives in spinal fluid and in diluted sera and should not be used for these specimens.[114] In contrast with that seen with complement fixation, the magnitude of the IgM titer does not correlate with an increased risk of dissemination.[135] IgM may persist in some patients with disseminated infection or may reappear with reactivation of infection. On occasion, IgM has been detected in cord blood of newborns whose mothers had detectable antibody. These infants had no evidence of infection on follow-up.[114] The enzyme immunoassay is a sensitive and rapid method for the detection of IgM. The interpretation of isolated positive IgM serologies is controversial. In a study of 706 enzyme immunoassays including 28 isolated IgM seropositives, Blair did not detect any false-positives.[19] In contrast, Kuberski found that 82 percent of patients with a positive IgM response and a negative IgG response had no evidence of coccidioidomycosis.[98]

Antibodies measured by complement fixation are slower to develop and primarily are in the IgG fraction.[114] Usually, they are not detected in serum samples obtained during the first week of illness, may appear as late as 3 months after onset of symptoms,[86,136] and typically last 6 to 8 months.[114] Early therapy with fluconazole may interfere with the development of IgG antibodies.[143] These antibodies are seen more commonly in symptomatic infections and are detected in 50 to 90 percent by 3 months after the onset of symptoms. At least 90 percent of persons show a positive IgM or IgG response after having symptomatic primary infections.[114,126] The main methods of detection of IgG antibodies are complement fixation, quantitative immunodiffusion, and enzyme immunoassay.[106,114,156,161] These assays correlate well, and immunodiffusion, particularly, is useful for detection of antibody in patients whose sera are anticomplementary.[114]

An IgM or IgG response is present in 90 percent of symptomatic coccidioidal infections.[115,127] The magnitude of the complement fixation antibody response correlates closely with the severity of infection and the likelihood of dissemination.[136] Although the antibody titer cannot be used as the sole indicator of dissemination, titers of 1:32 or greater in most laboratories are highly suggestive of extrapulmonary spread of infection[85,136]; 61 percent of these patients have a titer of at least 1:16, whereas 95 to 100 percent of those without dissemination have a titer lower than 1:16. The titer of complement fixation antibody parallels disease activity and is useful in following the progress of patients with disseminated disease. A few patients, especially those with extensive pulmonary involvement and pleural effusion, develop high titers without other clinical evidence of dissemination.[114] Conversely, some patients with dissemination, particularly those with single lesions in skin, bone, or meninges, have lower titers. These antibodies are measured by complement fixation or immunodiffusion.

More recently, enzyme immunoassays have become available. These assays compare well with more traditional assays and do not suffer from the subjectivity required to interpret the other assays.[64,106] The IgG enzyme immunoassay has a sensitivity of 92 percent, whereas the IgM assay has a sensitivity of 77 percent. When both assays are combined, the sensitivity is excellent,[93,106] but it is confounded by false-positive results in patients with blastomycosis or suspected noncoccidioidal pulmonary illness.[93]

Some patients with immunodeficiency disease, in particular HIV infection, may have extensive disease with low or undetectable antibody levels.[3,114] Bone marrow transplant recipients may yield no serologic or skin test response before or shortly after bone marrow transplantation, and aggressive attempts may be required to culture the fungus for diagnosis.[121]

The complement fixation antibody is detectable in the CSF of 70 percent of patients at the time of diagnosis of coccidioidal meningitis and eventually becomes detectable in almost all. The antibody measured is not a reflection of serum levels but rather is thought to indicate specific immunoglobulin biosynthesis by cells residing within or contiguous to the central nervous system. On occasion, patients with vertebral osteomyelitis or epidural abscesses yield low complement fixation titers in the CSF without other evidence of meningeal involvement.[114]

Antigen Detection

Antigen detection assays using *Coccidioides* galactomannan have been developed for detection of antigenuria and antigenemia. On the basis of preliminary data, they appear promising with detection rates of 50 to 71 percent for antigenuria and up to 73 percent for antigenemia when the specimen is treated with heat in the presence of EDTA. This assay still awaits validation.[55]

TREATMENT

Primary Infection

In more than 90 percent of children, primary coccidioidomycosis is a self-limited illness, and antifungal therapy is not needed. In some children with severe primary disease, therapy with antifungals may be justified either to abbreviate the period of morbidity or to lessen the chance of dissemination in those with an elevated complement fixation titer.

Which patients with primary uncomplicated pulmonary infections should receive therapy remains controversial. In general, evidence of severe infection or of concurrent risk factors such as immunosuppression should lead to the initiation of therapy. Severe infections usually are heralded in adults by weight loss of more than 10 percent, intense night sweats for a duration of longer than 3 weeks, infiltrates involving more than half of one lung or portions of both lungs, prominent or persistent hilar adenopathy, complement fixation titers of greater than 1:16, failure to develop normal skin test hypersensitivity to coccidioidal antigens, inability to work, or symptoms that persist for longer than 2 months.[69] Diagnosis of primary coccidioidomycosis during the third trimester of pregnancy or immediately post partum should prompt consideration of treatment. Amphotericin B is recommended for pregnant women in the first trimester because of the teratogenic potential of fluconazole, which is classified as a class D agent.[12] Thereafter, an azole antifungal or amphotericin B can be used. Fluconazole can be used in breast-feeding women, but other azoles should be avoided.[12] Because of their high risk for dissemination, persons of African or Filipino ancestry should be considered for antifungal therapy, which typically consists of oral azoles for 3 to 6 months. When reticulonodular or miliary disease is seen, therapy usually is initiated with amphotericin B or high-dose fluconazole. Amphotericin B seems to yield a faster response and is replaced by an azole after a few weeks.[69] The total course of therapy should last for at least 1 year and should be followed by oral azole therapy for secondary prophylaxis.[69] Immunocompromised patients, such as those with AIDS, recipients of solid-organ transplants, patients receiving high-dose steroids, or those receiving TNF-α inhibitors, warrant therapy.

Asymptomatic pulmonary cavities generally do not require therapy. Consideration should be given to excision of some cavities that persist for longer than 2 years, are progressively enlarging, or are adjacent to the pleural cavity. In patients with cavities that result in local discomfort, superinfection, or hemoptysis, therapy with oral azoles may alleviate the symptoms. Resection of localized cavities is an alternative to recurrent courses of antifungal therapy.[69] Pyopneumothorax results from rupture of a cavity into the pleural space. Its treatment is surgical with or without a course of antifungal therapy. Chronic fibrocavitary disease usually is treated with oral azoles for at least a year. In patients with inadequate responses, increasing the dose of azole, switching to a different azole, and administering amphotericin B are options. Surgical resection may be helpful in localized disease or when significant hemoptysis has occurred.[69]

Disseminated Disease

Nonmeningeal Dissemination

Patients with disseminated disease who have clinically apparent lesions outside the thoracic cavity almost always should receive antifungal therapy, usually with an azole (fluconazole or itraconazole). In fulminant infections, amphotericin B is the agent of choice as it is thought to result in more rapid improvement.[69]

The classic therapy consists of amphotericin B deoxycholate administered initially at a dose of 1 to 1.5 mg/kg/day and then tapered to 1 to 1.5 mg/kg/day three times a week. The usual duration of therapy is 3 months to 1 year. In children, a maximum duration of amphotericin therapy has not been defined because children are better able to tolerate the toxicities of amphotericin B. Local instillation or irrigation of abscesses and cavities with amphotericin B or other antifungal agents may be beneficial but has not been studied systematically.[17,89] Most patients respond to between 15 and 45 mg/kg, with total duration of therapy determined by the patient's response. Amphotericin lipid-complexed preparations offer the possibility of administering higher doses with less toxicity and have largely replaced intravenous amphotericin B deoxycholate.

The azoles have been tested extensively in this form of the disease. The main agents used are fluconazole and itraconazole. In a randomized, double-blind study of progressive nonmeningeal coccidioidomycosis, a trend toward better efficacy with itraconazole, especially in the subgroup of patients with skeletal infections, was demonstrated.[70] This approach must be weighed in children against the need for more frequent drug administration and dietary limitations related to the erratic absorption of itraconazole and its higher cost. Itraconazole has important drug interactions, most notably with tacrolimus, cyclosporine, and phenytoin.[76] Reports suggest that voriconazole and posaconazole can be effective therapies in patients refractory to fluconazole therapy.[5,97,141] A single case report demonstrated beneficial results with the concurrent use of interferon-γ.[99] In general, the azoles are used for a few months after resolution of symptoms or for at least a year of therapy. Fluconazole should not be used in the first trimester of pregnancy as cases of multiple congenital malformations somewhat reminiscent of the Antley-Bixler syndrome

have been described.[12] The role of echinocandins is unclear at present.

Surgical therapy seldom is required in patients with primary disease, but therapeutic thoracentesis may be indicated rarely when pneumonitis is complicated by large pleural effusions. Surgery also is necessary when pericardial involvement is complicated by tamponade. Patients with persistent coccidioidal cavities (>1 year) may require lobectomy, especially if the lesions are symptomatic.[69] Coccidioidal lymphadenopathy occasionally requires excision. In general, bone and joint disease requires a combined surgical and medical approach. Coccidioidal arthritis typically responds poorly to systemic therapy, and synovectomy may aid in the control of symptoms.[17,18] Osteomyelitis optimally is dealt with by curettage and drainage of the involved bone, with the addition of amphotericin B therapy, itraconazole, or fluconazole.[17,27,49,70]

Within endemic areas, routine serologic screening and primary prophylaxis are not indicated for HIV-infected children[29] and those receiving TNF-α inhibitors. Treatment is recommended for all HIV-infected individuals with active coccidioidomycosis and CD4 counts of less than 250 cells/μL. Once the infection is controlled, discontinuation of the therapy is reasonable if the CD4 count has risen to more than 250 cells/μL, except in cases of meningitis, in which the therapy should be lifelong.

Azoles have been used for both primary and secondary prophylaxis in endemic areas for patients with solid-organ transplants. The duration of prophylaxis usually is 6 to 12 months or more, but the optimal duration is unknown. Because of inhibition of the cytochrome P-450 system, levels of cyclosporine and tacrolimus should be monitored.[20]

Meningeal Disease

Amphotericin therapy for coccidioidal meningitis has been associated with a marked improvement in survival rates.[58,66] However, this requires prolonged intrathecal therapy through lumbar, ventricular, or cisternal administration. This therapy is associated with significant side effects that include headache, nausea, vomiting, chills and fever, arachnoiditis, and, occasionally, paralysis, seizures, and coma. The symptoms of arachnoiditis may be indistinguishable from those of microbiologic relapses.[80,91]

Studies using 400 mg of fluconazole or itraconazole in the treatment of meningitis without concurrent use of amphotericin B have shown good results, with response rates of approximately 80 percent.[71,146,147] Some experts prefer starting at a dose of 800 to 1200 mg of fluconazole or 600 mg of itraconazole.[91] Fluconazole currently is the preferred drug.[69] On the basis of limited data, the pediatric dose of fluconazole is approximately 12 mg/kg/day.[125] Patients generally respond clinically within 1 to 2 months, although abnormalities of the CSF may persist in some patients for a prolonged period. When therapy has been stopped, increases in CSF cell count or complement fixation antibody titer may be the only indications of reactivation of meningeal disease and signify a need to intensify therapy.[54] Some investigators use intra-CSF administration of amphotericin in conjunction with azole therapy in the hope of achieving a faster response.

Significant attention should be paid to CSF flow dynamics because almost all children with coccidioidal meningitis develop obstructive hydrocephalus, which requires ventriculoperitoneal shunting and rarely a second shunt to drain a "trapped" fourth ventricle.[80,128] Hence, the advantage of a drug such as fluconazole, which can be given systemically, obviates the problems of impaired CSF flow faced when intrathecal or intraventricular therapy is used. Monitoring of CSF pressure is important in assessing the timing of CSF shunting; persistent pressures above 200 mm of water herald the need for shunting.[91]

Studies have indicated that the relapse rate after discontinuation of azole therapy is high. Of 14 persons treated for coccidioidal meningitis with azoles (ketoconazole, itraconazole, or fluconazole) for periods ranging from 8 to 101 months, 11 (78%) had a relapse of disseminated coccidioidomycosis within 0.5 to 30 months after therapy was stopped. There were no clinical or laboratory predictors of patients at risk for having a relapse. The data thus indicate that moderately prolonged azole therapy for coccidioidal meningitis suppresses but does not eradicate the infection, suggesting the need for prolonged if not lifelong therapy.[51] Voriconazole and posaconazole have been used as rescue therapies in coccidioidal meningitis with some success; their role in central nervous system infections remains to be defined.[42,97,118,129,141]

PROGNOSIS

Primary pulmonary coccidioidal infection usually is self-limited, with complete recovery occurring in 1 to 3 weeks. In a small proportion of cases, localized complications of the primary infection, such as pleural effusion or pericarditis, prolong the clinical course. Dissemination is a rare event in whites and is less likely to occur in patients with erythema nodosum. Until the late 1950s, no effective therapy was available for the more severe forms of coccidioidomycosis, and the mortality rate of patients with disseminated disease was approximately 50 percent.[61] The mortality rate of patients with multiple sites of dissemination and those with coccidioidal meningitis approached 100 percent. Presently, therapy with amphotericin B or azoles may cure some of these patients and in many others prolongs useful life. Certain forms of disseminated infection, such as synovitis, are resistant to systemic therapy and may persist for many years without other signs of dissemination. For patients with HIV infection, therapy for disseminated coccidioidomycosis usually is not curative, and lifelong suppressive therapy with intermittent doses of amphotericin B or oral azoles may be required to prevent relapses in those with CD4 counts of less than 250 cells/μL. Those with counts above 250 cells/μL have a clinical course that is similar to that of immunocompetent individuals.[107] The prognosis for pregnant women has markedly improved with antifungal therapy.[12] The azoles are a major advance in the therapy

for coccidioidal meningitis, although they are fungistatic and thus require lifelong administration, sometimes failing to maintain remission of disease. Solid-organ transplant recipients remain at risk for disseminated disease and increased mortality when coccidioidomycosis develops after transplantation.

PREVENTION

Prevention of primary coccidioidal infection with antifungal agents or physical barriers such as masking is not practical. In endemic areas, control of dust, avoidance of wind storms, and avoidance of soil digging can decrease the risk for infection. Vaccine efforts are continuing but have not yielded a viable candidate vaccine to date.

CHAPTER 201

Paracoccidioidomycosis

Gil Benard • Maria José Soares Mendes-Giannini

Paracoccidioidomycosis, formerly known as South American blastomycosis, is usually a progressive chronic disease that preferentially affects the lungs, skin, mucous membranes, adrenals, and reticuloendothelial system. Benign, self-limited infections also have been occasionally documented. Two types of clinical presentations are described: the acute-subacute (juvenile) and the chronic (adult) forms of the disease. Children generally present with the acute form, which affects predominantly the reticuloendothelial system organs. Children account for about 5 to 10 percent of cases, and both sexes are infected; the systemic form of paracoccidioidomycosis occurs in about 70 percent of episodes.[16,83,168,169] The mycosis is limited geographically to various Latin American countries.*

The disease was described originally by Lutz in Brazil in 1908 and initially observed in children in 1911 by Montenegro.[110]

THE ORGANISM

The *Paracoccidioides* genus consists of dimorphic fungi, the etiologic agents of paracoccidioidomycosis. Currently, phylogenetic studies divide the *Paracoccidioides* genus into two species, *Paracoccidioides brasiliensis* (S1, PS2, and PS3 phylogenetic species) and *Paracoccidioides lutzii* (Pb01-like). Recombination events in *P. brasiliensis* species S1 and PS2 and *P. lutzii* were detected, whereas the *P. brasiliensis* species PS3 was considered to be clonal.[130,218,222]

The recognition of *Paracoccidioides* spp. as anamorphs in the phylum Ascomycota, order Onygenales, family Ajellomycetaceae has been accomplished by means of molecular tools.[27,230] *Paracoccidioides* spp. are phylogenetically closer to *Lacazia loboi* than to *Blastomyces dermatitidis*, *Emmonsia parva*, and *Histoplasma capsulatum*.[27,191] The fungus has four or five DNA chromosomes showing molecular sizes ranging from 2 to 10 Mb.[46,80,145] The genomes range in size from 29.1 to 32.9 Mb and encode 7610 to 8130 genes,[71] which is in agreement with the estimated gene number for ascomycete fungi genomes.

Paracoccidioides spp., thermally dimorphic fungi, appear as round to oval yeast cells of variable size (6 to 40 µm) in tissues and culture specimens at 37° C (98.6° F); in the environment or in vitro at temperatures lower than 24° C (75.2° F), morphologic features change to the mold form on culture under starvation conditions in minimal media. Conidia and mycelial fragments are considered the infectious particles. Once inhaled, they reach the alveoli, where, at the host tissue's temperature (37° C), they change from the saprophytic form to the parasitic multiple budding yeast form capable of producing disease.

Different groups have addressed the overall scenario of gene expression in *Paracoccidioides* spp. yeast versus mycelium or undergoing phase transition in vitro, making use of different molecular methods.* Many genes related to conidia[99] and in the parasitic phase in vitro[36,61,209] as well as in vivo models of infection† were also described. In the mycelial phase, growth is slow, requiring approximately 3 to 4 weeks; the colony is white to tan and compact, with short aerial mycelia. On microscopic examination, hyphae are fine (0.8 to 2.5 µm in diameter), septate, interlaced, and hyaline. Chlamydoconidia (20 to 50 µm in diameter), round to subspherical, terminal and intercalary, as well as arthroconidia may be observed.[110,184] Some isolates can produce aleurioconidia, uninucleate pear-shaped pedunculated or terminal structures, after long periods of incubation and under nutritional deprivation (media with reduced carbohydrate content).[37,110,184] The small size of these conidia (<5 µm) renders them compatible with alveolar deposition; furthermore, such conidia have been shown to be infectious when they are inhaled.[133]

The mycelial phase is not distinctive, and subcultures at 37° C are required for complete identification. At this temperature, *P. brasiliensis* produces soft, wrinkled, cream-colored colonies that develop in approximately 6 to 10 days. On microscopic examination, the most characteristic feature is the presence of multiple budding yeast cells; the parental cell produces various peripheral buds and acquires the appearance of a pilot's wheel. *P. brasiliensis* may possess alternative control mechanisms during cell growth to manage multiple budding and its multinucleate nature.[1] Single buds and short chains also are produced, but they are not diagnostic. Cells are variable in size (2 to 40 µm) and have a thick cell wall and internal vacuoles.[176] Elongated conidia were observed exclusively in *P. lutzii* isolates.[222] This phase of growth is identical to the one observed in tissue and pathologic materials.[37,88,110,177,184] The organism does not readily take most bacterial or hematologic stains. *P. brasiliensis* is aerobic and, in its mycelial phase, grows well in the regular mycologic media to which antibiotics and cycloheximide have been added to reduce growth of bacteria and saprophytic

fungi.[37,110] Isolation should be attempted by the use of modified Sabouraud agar, yeast extract (15%) agar plus antibiotics and cycloheximide, yeast extract–phosphate agar, brain-heart infusion agar plus blood and antibiotics, or tryptic soy agar plus fungus water extract and horse serum, incubated at room temperature.[110,184]

TRANSMISSION

Paracoccidioidomycosis is not a contagious disease.[37,88,110,184,234] A single case of placental involvement that did not result in fetal infection has been reported.[31] Epidemic outbreaks have not been reported, and only a few cases in family members have been documented,[110,113,114,234] which could be attributed to the long periods of mycosis latency between the moment of infection and the appearance of overt clinical manifestations.[183] Consequently, the patient's memory of the activity contributing to the infection or of the accompanying individuals usually has been forgotten, which prompted Borelli[35] to coin the name "reservarea" for those places in the endemic areas where the fungus has its habitat and humans acquire the infection. This concept differs from that of an endemic area, which implicates the place where the disease is diagnosed.

P. brasiliensis infection in animals as proved by culture or histologic examination has been shown consistently in armadillos, mammals that probably acquire the infection when they disturb the terrestrial habitat of the fungus,* and more recently in a dog.[66,189,190] Unfortunately, the microniche of *P. brasiliensis* has not been identified properly; soil has been incriminated, but the number of isolates from this source is small.[211,234] The inhibitory effect of pesticides on *P. brasiliensis* may suggest that they can interfere with attempts to isolate *P. brasiliensis* from soil.[161,221] The role played by deforestation in increasing both exposure and incidence rates has been documented in Brazil in Amerindians and in children.[54,84,192] Some studies are related to presence of the fungus in environmental aerosol samples[3] and climate change.[12,13]

Species-specific inner primers derived from rDNA regions (internal transcribed spacer [ITS], 5.8S gene) have been described, and the nested polymerase chain reaction (PCR) sensitivity was higher for the detection of *P. brasiliensis* in soil than culture and animal inoculation. The fungus was detected in soil artificially seeded (positive soil control) and from environmental samples collected in an armadillo burrow.[221] This approach probably would improve the fungal microniche studies. The ecologic factors that prevail in the reservarea also have been characterized, with the following being significantly associated with the disease: altitude from 1000 to 1499 meters above sea level, annual rainfall from 2000 to 2999 mm, and presence of humid forests and of coffee and tobacco crops.[43] Environmental correlates (soil texture and precipitation) indicate that moisture availability plays an important role in paracoccidioidomycosis distribution.[212] The fertile regions of endemic areas have the highest incidence rates of paracoccidioidomycosis.[43,224]

*References 6, 7, 41, 152, 182, 192, 211, 219.

Paracoccidioidomycosis was thought, and still is by some, to be acquired by trauma. However, clinical and experimental data indicate that infection is acquired most commonly by inhalation.[37,96,112,178,185]

EPIDEMIOLOGY

Age

More than 70 percent of the patients are 30 years of age or older. The number of childhood cases was shown to vary from 2.1 to 3.4 percent in the first decade of life.* In 1976, Castro and del Negro[51] published one of the largest series of children with paracoccidioidomycosis diagnosed in a 30-year period. They found that among 1899 patients with this disease seen at the Hospital das Clinicas in São Paulo, Brazil, only 70 (3.6%) of the patients were 14 years of age or younger. However, in 1999 and in the same state, Blotta and colleagues[32] found that 5.6 percent of the paracoccidioidomycosis patients diagnosed between 1988 and 1996 were younger than 14 years, thus showing an increase from the 1976 figure. In 1998, Rios-Gonçalves and associates[192] analyzed the records of 36 children who had been diagnosed in the state of Rio de Janeiro during a period of 25 years. In a similar period, Fonseca's group[84] described 13 children, 12.7 percent of all cases, who had been diagnosed in the Amazonian states of Pará and Tocantins, forest areas that have been colonized since the 1970s and where paracoccidioidomycosis formerly had been regarded as rare. In certain places, the infection rates measured by a positive skin test reaction also were high. In 1976, Pedrosa[167] conducted a skin testing survey among rural children (6 to 11 years of age) in a particular county of Rio de Janeiro where paracoccidioidomycosis had been diagnosed previously in a 3-year-old boy. He found that 34 percent of the children tested positive for paracoccidioidin, a figure indicative of early exposure to *P. brasiliensis*.

In 1996, Londero and colleagues[114] compiled the records of 106 children with the mycosis, including those formerly analyzed by Castro and del Negro.[51] This series, some compilations,[24,156,168,169] several individual reports, and a thesis[11] have revealed that the disease occurs more frequently in individuals 12 to 15 years of age than in younger children (Table 201-1). More than 250 reports of paracoccidioidomycosis in children aged 3 to 14 years, including those analyzed by Londero and colleagues,[114] have been found in a literature search. Bellissimo-Rodrigues and colleagues[16] described, among 1219 patients studied, 196 patients (16%) younger than 21 years and 42 patients (3.4%) 3 to 10 years of age. Other studies appointed values of 15.4 to 20 percent in the midwest or southeast regions of Brazil.[32,164] The prevalence of infection with *P. brasiliensis* was evaluated in a cross-sectional study of 298 asymptomatic schoolchildren in the Brazilian Amazon region. The reactivity of children to two different *P. brasiliensis* antigen preparations, paracoccidioidin and a purified 43-kDa glycoprotein (gp43), was 4.6 percent. However, in the group of

TABLE 201-1 **Age and Gender Distribution of 354 Children with Paracoccidioidomycosis**

Gender*	Age		Total by Gender (%)
	3-9 yr	10-14 yr	
Male	95	125	220
Female	63	71	134
Total by age	158 (41.8%)	196 (58.2%)	354 (100%)

*Male-to-female ratio = 1.6:1.
Data from references 32, 53, 55, 84, 143, 157, 167, 168, 193, 194.

individuals receiving paracoccidioidin who had a positive histoplasmin skin test result, the prevalence of exposure to *P. brasiliensis* was 44 percent, suggesting that the use of the paracoccidioidin preparation may result in cross reactions with other environmental fungi.[105]

The relative paucity of children with this mycosis in comparison with the figures reported in adults* may be explained, in part, by the effective control exerted by most hosts on the progression of the primary infection, by the long incubation period characteristic of the mycosis, and by the establishment of latent foci that may become apparent clinically many years after initial exposure.† Benard and associates[23] considered that the association with different age groups is related to the epidemiology of paracoccidioidomycosis because in the endemic areas, as previously shown, children become exposed to the fungus at an early age. In healthy children, appropriate defenses usually curtail development of the mycosis; but in infants of low socioeconomic conditions, the transition from infection to overt disease may be accelerated and aggravated by the mycosis itself, by malnutrition, or by other associated conditions.‡ In addition, unknown susceptibility factors, the intensity of exposure to the infectious source, the virulence of certain *P. brasiliensis* isolates, and other factors may well contribute to the development of the disease in children.§

Gender

Adult men are afflicted with much greater frequency than are women.¶ In children, however, the disease affects boys and girls in approximately equal proportions.** In the review published by Londero and associates,[114] which included children up to 14 years of age, a slight predominance of male patients was noted in the older group (see Table 201-1). These findings suggest that sex hormones, hormone-dependent immunologic factors, or both play a role in determining the outcome of the host-parasite interaction.[4,5,19,37] Researchers have shown in vitro that estrogens inhibit *P. brasiliensis* mycelium to yeast transition, thereby hindering the progression of the infection.[4,37,202] Analysis of the mortality profile from paracoccidioidomycosis according to gender and age showed similar death totals for both genders in the groups younger than 20 years. The majority of deaths among male patients (97.14%) occurred in individuals older than 15 years, with only 2.37 percent among individuals younger than 15 years. Among female patients, most deaths from paracoccidioidomycosis (89.21%) also occurred in those older than 15 years, but 9.75 percent did occur in those younger than 15 years; that rate is nearly five times the percentage observed in males. These findings corroborate the literature, according to which the infection and disease occur equally between the genders during childhood, with a slight predominance of males with the disease, compared with an absolute predominance of males among adults with the chronic form of the mycosis.[59]

Occupation and Race

Almost half of the reported cases in adults occur in individuals whose occupations require extensive exposure to the soil. Adult residents of areas in which paracoccidioidomycosis is endemic generally develop disease less severe than that seen in immigrants or in people who migrate to highly endemic settings. These people often develop disseminated infection, much like the juvenile cases do. The proportion of acute-subacute cases observed in the study of Bellissimo-Rodrigues[16] (26.4%) might be explained by the higher proportion of children, women, and Afro-descendants. The influence of genetic traits on the mycosis has not been elucidated,[72] but in patients with the unifocal chronic form of the disease, a mild clinical presentation in which lesions are restricted or localized, the HLA allele most commonly seen was DRB1*11, suggesting that the participation of HLA antigens may influence the outcome of the host-parasite interaction in paracoccidioidomycosis.[196]

Geographic Distribution

Paracoccidioidomycosis is restricted to Latin America, from Mexico to Argentina; some countries within this area (Chile and some of the Caribbean islands), however, are free of the disease. In endemic countries, the disease distribution is uneven; most cases occur in individuals living in regions corresponding to the humid tropical and subtropical forests. The endemic area is centered in Brazil; 7000 of the about 10,000 patients described to date were natives of this country.* New endemic areas have been reported in the Amazon region, where the mycosis was considered to be rare. In Brazil, this fungal infection is considered to be an important cause of mortality among infectious diseases, with a rate of 1.45 cases per million inhabitants.[30,119,129] Paracoccidioidomycosis represented the most important cause of deaths among systemic mycoses[59,174] (approximately 51.2%).

Although paracoccidioidomycosis has been reported in patients not living in endemic areas, prior residence in Latin America has been documented in every case.* In some of these patients, the interval between residence in the endemic area and clinical manifestations of the disease has been 10 to 40 years.[39,110,184] Within endemic areas, 2.0 (children) to 82 percent react to the intradermal administration of paracoccidioidin, suggesting previous contact or subclinical infection with *P. brasiliensis*.†

P. brasiliensis is a complex species,[130] and phylogenetic studies have revealed that this species actually contains at least four cryptic phylogenetic species: two paraphyletic species, S1 (species 1) and PS2 (phylogenetic species 2); and two monophyletic species, PS3 (phylogenetic species 3) and the Pb01-like species for which the name *P. lutzii* sp. nov. has been proposed.[130,218] The cryptic species were present in different regions: S1, in Brazil, Argentina, Paraguay, Peru, and Venezuela; PS2, in Brazil and Venezuela; PS3, restricted to Colombia; and Pb01-like group, another species, *P. lutzii*, in the central region of Brazil.[218] Despite the apparently restricted ecologic niche, the habitat of the etiologic agent has not been determined precisely.[12,83,186]

PATHOGENESIS AND PATHOLOGY

The initial stages of the host-parasite interaction are unknown because of our inability to detect the precise moment when infection does occur.[8] In the past, traumatic implantation of the fungal propagules into skin and mucosa was thought to cause primary lesions, whereas other manifestations were regarded as secondary. However, through the study of many cases, including autopsies, what has become apparent is that pulmonary lesions are primary, with the infection taking place by inhalation of fungal propagules.[37,90] In experimental animals, the inhalatory route has been shown to give rise to disseminated disease.[133] In most cases, the initial pulmonary infection does not cause undue symptoms.[87,113] Once the conidia reach the terminal bronchi or the alveolar spaces, yeast transformation ensues.[133] In some cases, the fungus promptly disseminates by the lymphohematogenous route, producing distant subclinical and quiescent foci. Apparently, the local defenses are capable of controlling fungal spread, but some viable yeast cells may remain dormant in such foci in the pulmonary and mediastinal lymph nodes. Rarely, the initial pulmonary infection outweighs the host's immune defenses, causing an acute-subacute disease, the juvenile type, with predominant involvement of the reticuloendothelial system.[88] The disease in children falls into this category. Often, the quiescent foci remain so throughout life, as demonstrated by the high number of subclinical infections compared with the low disease incidence of this mycosis in the endemic regions.[86,234] Nevertheless, the most common clinical presentation of the disease is the chronic form, or adult-type disease, believed to result from fungal reactivation in these foci.[87] This reactivation frequently occurs when the patient has left the endemic area, as demonstrated by the cases reported outside Latin America, in countries where paracoccidioidomycosis is considered an imported disease.[52] Of note, these cases may be manifested decades after leaving the endemic area, leading to difficult and delayed diagnosis.[101]

Thus, in the acute or subacute form, the initial lung infection may pass unnoticed but is followed by prompt dissemination to other organs and tissues.[21] In the chronic form, lung disease frequently occurs. Disease is restricted to the lungs in some of these patients, but in most, other organs also are afflicted. This may be caused by lymphohematogenous dissemination from reactivated pulmonary foci or directly from foci at virtually any organ. Actually, paracoccidioidomycosis, in the acute, subacute, or chronic form, is more frequently a disseminated disease, even though clinical manifestations appear to be restricted to a sole organ.[88,135] However, determination of the degree of dissemination certainly is influenced by the availability of diagnostic procedures. After appropriate therapy, residual lesions, mostly fibrotic, become established.[87,135]

As already mentioned, the disease in children is acute or subacute and progressive (the juvenile form).[24,51,114] The time that elapses between infection and the onset of symptoms is not known precisely but has been estimated to be short in most cases, such as a few months.[87,88] In such patients, paracoccidioidomycosis is a severe, systemic disorder that involves preferentially the reticuloendothelial system to such an extent that it is the hallmark of the process.[11,24,114]

In adults, pulmonary lesions as seen on chest plain films may be defined as micronodular or miliary, nodular, infiltrative or interstitial, cavitary, fibrotic, and mixed types.[135,229] Emphysematous areas, pleural thickening, and enlarged hilar and mediastinal lymph nodes also can be observed. These alterations can be better visualized by computed tomography imaging.[89,213] Lung involvement probably is secondary to a chronic lymphangitic process provoked by the fungus itself and the host's response represented by formation of granulomas and fibrosis, the latter of which predominates at the perihilar region. This aspect correlates with the butterfly-like (perihilar) micronodular and interstitial infiltration observed on plain films.[228] Obstruction and reversal of lymphatic flow would lead to the spread of the inflammatory process throughout the lungs.[228]

In children and adolescents, the pulmonary component tends to pass unnoticed, and neither clinical examination nor radiologic studies reflect the real damage.[90] Actually, only a minor proportion of the cases reported have had lung symptoms[114] (Fig. 201-1). However, lack of notification may be more apparent than reality because the weight of the extrapulmonary lesions tends to minimize the less intense respiratory manifestations. Frequently, the mycosis is misdiagnosed, especially for tuberculosis and certain lymphomatous disorders.[114] Nonetheless, a careful search of pulmonary samples, including induced sputum, may reveal the characteristic multiple-budding *P. brasiliensis* yeast cells.[114,188] Moreover, gallium scanning and computed tomography have allowed

detection of incipient or discrete interstitial pulmonary lesions not revealed by plain radiography.[89,236]

Lesions in the oropharyngeal and laryngeal mucosa occur frequently in the chronic form. They may be infiltrative, ulcerated, nodular, or vegetative and usually have a granulomatous aspect and may mimic squamous cell carcinoma.[28,135,142,200] The base of the ulcerated lesions usually is covered by small abscesses (the mulberry-like lesions) that probably represent fungal dissemination through the lymphatic system because they usually are accompanied by regional lymph node involvement.[50]

In children, such mucosal lesions are rather exceptional, but skin involvement occurs more commonly and tends to be multiple, in contrast with the adult chronic form,[135] in which lesions are represented mostly by contiguous involvement of the periorificial mucosal lesions or draining lymph nodes. In children or young adults, and eventually in adults with the chronic severe disseminated disease, they represent hematogenous spread of the fungus. In this case, the lesions may appear as ulcerated or ulcerovegetative lesions, papules, or crust-covered ulcers and warts, usually at the same stage of development. Skin involvement may rarely be manifested as sarcoid-like lesions.[153] Reports of septic shock caused by septicemia by *P. brasiliensis* show that the fungus can be blood-borne.[135,227]

The reticuloendothelial system is the target organ in both children and young adults.[11] Almost every child with paracoccidioidomycosis exhibits involvement of the superficial or deep lymph node chains. Lymph nodes vary in size, number, consistency, and location; with time, they may liquefy, forming abscesses or fistulas (Fig. 201-2). The spleen and liver frequently are involved in these same groups. Abdominal lymph node involvement also is a common occurrence in children.[11,114] Hypertrophied lymph nodes, usually generalized but particularly periaortic, around the hepatic hilum and retroperitoneally, can be detected by ultrasonography, computed tomography, or magnetic resonance imaging.[126] Coalescent masses may become palpable and may result in disease caused by extrinsic compression of adjacent structures, such as jaundice by compression of the biliary duct,[33] pancreatitis,[33] or intestinal obstruction.[127]

Splenic lesions are nodular or miliary. Gross hepatic lesions may not be apparent, but histopathologic examination regularly reveals fungal invasion of this organ.[11,24,114] In a series of fatal cases of paracoccidioidomycosis, 56.7 percent revealed the presence of yeast cells in the liver, associated with a granulomatous tissue response. Thirty percent of the cases had only widening of the portal tracts by fibrosis (31.6%), whereas 11.6 percent had an essentially normal liver.[217]

The intestinal mucosa may be affected, but similar to the lungs, its involvement is secondary to blockade of the regional lymphatic flow, with retrograde progression of *P. brasiliensis* to the mucosa, a process resulting in mycotic enteritis.[33,85,127] In this case, the submucosal inflammatory process is granulomatous; fungal cells are visualized; and the intestinal changes may vary from dilated loops, edema, congestion, and nodule formation to multiple mucosal ulcers.[85,127]

Studies also have shown bone marrow infiltration mainly but not exclusively in the acute-subacute form of the disease; 25.7 percent of the patients examined during active disease and 36.4 percent of those who died of paracoccidioidomycosis revealed this type of involvement.[180] Bone marrow necrosis has also been reported in the juvenile form.[181] The histology pattern was variable, but appropriate staining always displayed fungal cells. Bone marrow invasion frequently is associated with marked eosinophilia.[180,205] In addition, bone (Fig. 201-3) and joint lesions are frequent occurrences in the acute-subacute form of the disease[2,24,75,114,227] and appear closely related to bone marrow infiltration.[180]

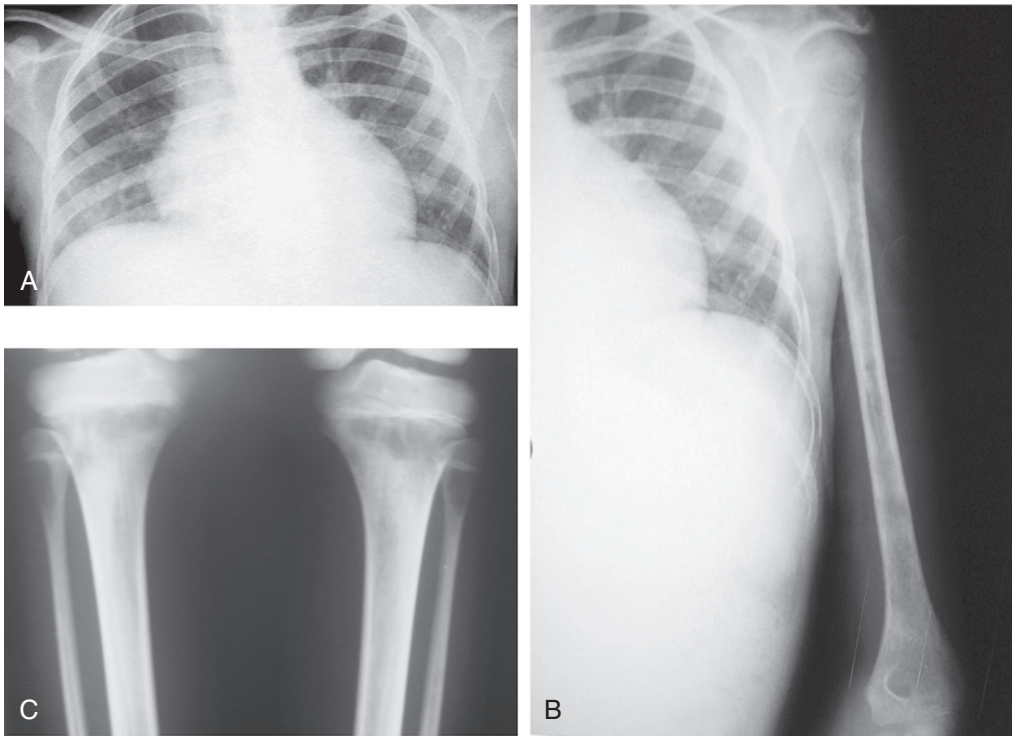

FIGURE 201-3 ■ Severe disseminated subacute paracoccidioidomycosis in a 9-year-old boy. The chest radiograph (**A**) shows mediastinal lymph node enlargement and mild bilateral infiltrates in the middle and lower fields. Osteolytic lesions of long bones: humerus (**B**) and tibia and fibula bilaterally (**C**).

The adrenals often are involved in patients with the chronic form of the mycoses, with a small proportion of the patients evolving to adrenal hypofunction or insufficiency (Addison disease). The glands contain multiple granulomatous foci, and diffuse necrosis may be seen in the most severe cases. Hyperplasia of the adrenal glands also occurs commonly.[135]

On histologic evaluation, formation of granulomas is the rule, except in patients with severe disseminated disease, such as those with the acute-subacute form.[88] The granulomatous inflammation is associated with a mixed pyogenic component, especially in the case of ulcerated skin lesions or ruptured lymph nodes. Caseation and central necrosis may be present. In compact granulomas, abundant epithelial cells, Langerhans or foreign body giant cells, plasmacytes, and lymphocytes are seen; often, phagocytosis of the yeast cells can be observed. $CD4^+$ lymphocytes dominate over $CD8^+$ lymphocytes and appear as peripheral mantles around aggregates of macrophages and histiocytes.[149] In the juvenile disseminated disease, the inflammatory reaction is diffuse, with abundance of both mononuclear and yeast cells but sparse formation of compact granulomas.[23,51,187] Loose granulomas appear unable to circumscribe fungal antigens, and at their periphery, *P. brasiliensis* antigens may permeate throughout the intercellular space.[199] Skin and mucous membrane lesions usually exhibit pseudoepitheliomatous hyperplasia and intraepithelial microabscesses.[163,166,199]

An interesting aspect drawn from the previously described histologic studies is the frequent description of areas of extremely active disease characterized by pyogenic reaction and loose granulomas, rich in budding fungal cells, intermingled with areas with compact granulomas, rare fungal cells, and variable degrees of fibrosis. This mixed aspect can be observed in lymph nodes, skin, or pulmonary lesions, suggesting that the disease evolves through localized new bouts of fungal multiplication and tissue invasion, whereas the adjacent older lesions are on their way to fibrotic resolution. Computed tomographic imaging of the lung confirmed this aspect by depicting areas with alveolar condensation along with fibrotic and emphysematous zones and the simultaneous presence of features of more recent and chronic lesions.[89,213]

Tissue reactions are nonspecific; thus, diagnosis depends on finding *P. brasiliensis*. If the parasite is abundant, it may be identified by hematoxylin and eosin stains. Special fungal stains (e.g., Grocott silver methenamine), however, always should be employed, especially when granulomas are examined. The typical multiple budding yeast cells must be found to establish a diagnosis. The finding of fungal cells of different sizes (2 to 40 μm) suggests the presence of *P. brasiliensis*. In some cases, short chains and cells with single buds also are observed, and in these patients, differentiation of *P. brasiliensis* from *Cryptococcus neoformans*, *Blastomyces dermatitidis*, and even *Histoplasma capsulatum* and *Pneumocystis jiroveci* must be made.[113,208] When the disease is chronic, most of the fungal cells are found inside the macrophages, but free yeast cells predominate in disseminated cases. Internalized yeast cells exhibit altered morphology.[183]

CLINICAL MANIFESTATIONS

Paracoccidioidomycosis is a polymorphic disorder that at a particular time may involve more than one organ system. Thus, making a topographic classification is unrealistic, and the classification of the mycosis currently accepted takes into consideration not only the organs involved but also the host's immune condition and the disease's natural history.[87] The infection is categorized as a *subclinical form*, and the overt process is subdivided into *acute-subacute* and *chronic disease*. The acute-subacute pattern predominates in children and young adults, although the disease is also called juvenile form, whereas the chronic disease affects adults and aged people and is thus called the adult form. According to the severity of the process, juvenile patients are assigned to two subgroups: severe and moderate. The adult form may be localized to pulmonary lesions, unifocal disease, or disseminated from its primary foci, the multifocal process. Disseminated disease is characterized by involvement of the skin, mucosa, reticuloendothelial system, adrenal glands, and, less frequently, the gastrointestinal or genitourinary tract, bones, and central nervous system.* The chronic form can be mild, moderate, or severe.[87]

Patients with acute or subacute disease develop signs and symptoms of a wasting process. Fever, malaise, listlessness, weight loss, and emaciation are recorded frequently. The severity of these symptoms is proportional to the degree of the organ involvement. Londero and associates[114] gathered the information published up to 1994 and found 269 cases in children younger than 14 years; however, sufficient clinical data for analysis of the prominent organ involvement were provided for only 77 children. The clinical characteristics exhibited by these children and by other patients described more recently, including the series of patients at two centers, are shown in Table 201-2. These findings support the notion that juvenile paracoccidioidomycosis is a disease of the reticuloendothelial system resulting in damage of the corresponding organs caused by severe macrophage dysfunction, as suggested previously.[88] Superficial lymph node enlargement was the predominant sign (81.6%) in these cases. Cervical and submandibular lymph node chains were involved most commonly, followed by those of the supraclavicular and axillary regions; however, any chain can be affected (Fig. 201-1). Lymph nodes may vary in size from slightly enlarged to large, painful, coalescent masses; they may be mobile and of elastic consistency or fixed to the adjacent tissues. Hypertrophied nodes may progress to fistulization and discharge purulent material rich in *P. brasiliensis* yeast cells.

The next most important finding was hepatomegaly or splenomegaly (60.7%), which usually was asymptomatic. Jaundice is an infrequent occurrence and more closely relates to extrinsic compression of the biliary tree.[33] Liver enzymes, especially alkaline phosphatase, were abnormal in some cases but not markedly increased.[33,156] Portal hypertension also was a rare occurrence. Findings and complaints relating to the abdomen and digestive tract, such as presence of abdominal masses, lymph node enlargement, diarrhea, vomiting, abdominal distention or pain, and ascites, also have been recorded in a sizable proportion of patients (see Table 201-2 and Fig. 201-2). Signs and symptoms of an acute abdomen, caused by masses formed by hypertrophied lymph nodes or perforation, also have been reported; this problem may lead to intestinal occlusion, blockage of lymphatic drainage, and, later, ascites.[11,24,114,157,169]

In a series comprising predominantly patients with the juvenile form of the disease, abdominal radiographic studies (double-contrast barium) revealed ileal and jejunal alterations in 42 to 51 percent.[85,127] The main findings were distortion and coarsening of the mucosal pattern and loop dilation. However, part of these alterations was probably nonspecific because jejunal biopsies performed in a small number of patients revealed neither granulomatous response nor *P. brasiliensis* yeast cells.[127] On the other hand, histopathologic examination of autopsies (probably the more severe cases) showed a specific granulomatous enteritis in 80 percent.[85] In addition, in a magnetic resonance imaging study of patients, mostly with the juvenile form, 48 percent had abdominal lymph node enlargement, even if no abdominal signs and symptoms had been recorded.[28] This lymph node involvement can cause mesenteric lymphatic stasis and enteric mucosal edema that may progress to fungal enteritis accompanied by abnormal intestinal function, such as reduced absorption of fat.[128,157,169] Computed tomography and magnetic resonance imaging have proven helpful in determining the extent and nature of abdominal involvement.[126]

TABLE 201-2 **Clinical Findings on Admission Diagnosis of Children with Paracoccidioidomycosis**

Clinical Findings	No. of Children (%)
Lymph node enlargement	
Superficial	81.6
Thoracic	25
Abdominal	36.6
Abdominal masses	19.9
Hepatomegaly or splenomegaly	60.7
Ascites	19.1
Jaundice	10.5
Diarrhea, vomiting, abdominal pain, or distention	19.1
Joint or bone lesions	37.8
Skin lesions	29.1
Respiratory symptoms	9.1
Pulmonary consolidations or infiltrates	10.2
Pleural effusion	5.1
Oral and upper respiratory tract mucosa lesions	9.2

Total number of children investigated for each clinical finding varied from 98 to 199.
Data from references 2, 16, 55, 75, 84, 116, 143, 156, 168, 184.

*References 11, 31, 90, 135, 143, 187.

Abdominal complications continue to be occasionally reported in more recent series.[157,169]

Bone damage and articular problems also are important components (37.8%) of disseminated disease, especially in younger children. In these patients, the long bones were frequently affected, with the lytic lesions located at the diaphyseal or metaphyseal-epiphyseal regions,[2] probably because of their higher vascularization, emphasizing the hematogenous dissemination that typically occurs in this form of the disease (Fig. 201-3). Ribs, skull, phalanges, and vertebral lytic lesions also have been documented (Fig. 201-3). Different from the painful, motion-restriction joint lesions, the bone lesions usually were silent.[2,24,77,144] A pathologic fracture occasionally may occur.[144]

Skin lesions were noted in 29.1 percent of the juvenile cases, with a tendency toward higher frequency with increasing age of the patient. Distribution of cutaneous lesions was variable, but face and trunk were involved more frequently.[135] Lung abnormalities were recorded in a smaller proportion of cases. However, even in the absence of clinical and radiologic involvement, colonization of the lung by *P. brasiliensis* can be demonstrated by direct examination and by culture.[188] When chest radiographs were abnormal, enlarged hilar lymph nodes and miliary infiltrates predominated.[90,114,188] In contrast with the adult form of the disease, in which adrenal involvement is a serious concern, it is uncommon in children. A survey of adrenal function before and after treatment in 23 children has shown normal adrenal function.[170]

Anemia, an increased erythrocyte sedimentation rate, severe hypoalbuminemia, and hypergammaglobulinemia with high IgG serum concentrations are found regularly.[11,24,88,156] Nonetheless, anti–*P. brasiliensis* antibodies may prove undetectable in some patients.[68,69,155] Eosinophilia and elevated IgE antibody titers have been detected in most patients.[156,205,237]

The association between human immunodeficiency virus (HIV) infection and paracoccidioidomycosis has been investigated.[19,147] However, the youngest patient described was a 15-year-old boy who had enlargement of superficial and mediastinal lymph nodes, skin nodules, and pulmonary infiltrates.[53] The mycosis was also diagnosed occasionally in other patients whose immune function was depressed by certain conditions or medications.[125] The incidence of this mycosis has not increased in HIV-infected patients as would have been expected.[19] No report of paracoccidioidomycosis and HIV coinfection in children has so far been published. In the chronic, progressive, adult form of paracoccidioidomycosis, signs and symptoms differ substantially from those found in children. Descriptions of the disease in adults are beyond the scope of this text but are referenced.[88,135,200]

DIAGNOSIS

Specific diagnosis depends solely on laboratory confirmation. The "gold standard" for paracoccidioidomycosis diagnosis is the direct observation of characteristic multiple-budding cells in biologic fluids and tissue sections or the isolation of the fungus from clinical specimens. The large cell, with multiple exosporulation, resembling a pilot's wheel, is pathognomonic of the disease. Detection of antibodies against certain fungal antigens or the presence of such antigens in the patient's body fluids constitutes indirect diagnostic criteria. The direct microscopic observation of the characteristic *Paracoccidioides* spp. should be done in a drop of physiologic saline or potassium hydroxide test (Fig. 201-4).[110] Usually, the sources of clinical specimens are sputum, secretion and scraps or debris from ulcerated skin and mucosal lesions, draining material from suppurating lymph nodes or abscesses, bronchoalveolar fluid, and biopsy tissue as well as exfoliative cytology specimens.[47,68] Bronchoalveolar, articular, cerebrospinal, or other fluids must be centrifuged before examination. Draining material from suppurating lymph nodes usually is rich in fungal cells with multiple buds. Sputum is one of the most important specimens used for diagnosis, and various procedures are used to improve the detection of the organism in this specimen. A cell block preparation method for sputum proved more sensitive (93%) than simple direct examination,[215] but few laboratories have employed it routinely. When the first examination of the sputum is negative, it can be homogenized with an equal volume of *N*-acetyl-L-cysteine and then centrifuged again. Sodium or potassium hydroxide can be used, but only in direct examination because this treatment reduces the fungus isolation. The sensitivity of the direct examination (wet mount, smears, and histopathologic examination) varies from 80 to 100 percent or less and depends on the laboratory.[37,110,148] Biopsy samples should be taken only when routine direct examinations have failed, and the specimen should be placed in two separate flasks: one with sterile saline and the other with formalin buffered for mycologic and histopathologic examinations. As the morphologic appearance of the parasitic forms of *P. brasiliensis* is pathognomonic, the diagnosis of the mycosis can be established by biopsy specimen and confirmed by either culture or serology. If the parasite is abundant, it may be identified by hematoxylin and eosin stain and confirmed by a special fungal stain, such as periodic acid–Schiff or Gomori methods.[88,110,199] Pereira and colleagues[169] established

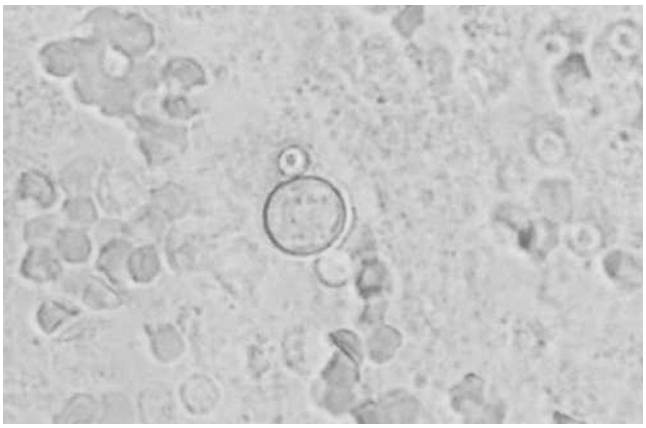

FIGURE 201-4 ■ Direct examination of a potassium hydroxide mount of a patient's sputum specimen showing a budding *Paracoccidioides brasiliensis* yeast form–like cell.

the diagnosis of 63 children with paracoccidioidomycosis by the identification of *P. brasiliensis* in lymph node biopsy (84%), bone biopsy (9%), or skin biopsy (7%) specimens.

When the disease is chronic, most of the fungal cells are found inside the macrophages, but free yeast cells predominate in disseminated cases. Pauciparasitic forms of the *Paracoccidioides* spp. granuloma that show a sarcoidic pattern with rare yeast forms may appear. In these cases, the diagnosis may rely on epidemiologic data plus serologic and molecular diagnostic tools such as PCR on paraffin-embedded tissue.[65,138,139] Visualization of the multiple budding yeast cells, in which the buds are connected to the parent cells by a narrow bridge with a well-defined refringent double wall, is mandatory because the *Paracoccidioides* spp. yeast cells may range from a few microns to 30 to 40 µm. Sometimes, in the lesions, the parasite is present as diminutive yeast cells, measuring about 3 to 5 µm.[110,183,184] *Paracoccidioides* spp. blastoconidia may be confused with *B. dermatitidis*, capsule-deficient *C. neoformans*, endospores and small *Coccidioides immitis* empty spherules, large *H. capsulatum* yeast cells,[37,110] or even *P. jiroveci*.[208] For this reason, the multiple budding structures always should be found for specific diagnosis. In these cases, the molecular tests such as PCR and immunocytochemistry with specific polyclonal or monoclonal anti–*P. brasiliensis* antibody could be used.[45,64,91,93,110]

Both disseminated and pulmonary paracoccidioidomycosis can be confused with tuberculosis, histoplasmosis, leukemia, malignant neoplasms, or Hodgkin disease. When the skin or mucous membranes are affected, paracoccidioidomycosis must be differentiated from histoplasmosis, leishmaniasis, leprosy, syphilis, lupus erythematosus, and a variety of malignant neoplasms. In children, tuberculosis, acute abdominal syndrome, intestinal obstruction, osteomyelitis, and rheumatic fever also are important considerations in the differential diagnosis of this disorder.

Culture samples should be obtained to support the diagnosis and to establish the viability of the fungus. However, they are not always positive because the presence of other more rapidly growing microorganisms in the samples renders isolation difficult. Culture methods, although essential to establish the diagnosis in some cases, have limitations for rapid diagnosis, namely, insensitivity, the need for invasive procedures, and delayed growth. At room temperature, *Paracoccidioides* spp. are slow-growing fungi that can be overgrown readily by bacteria, yeasts (especially *Candida*), and contaminant molds. Isolation should be attempted by the concomitant use of modified Sabouraud agar and yeast extract agar plus antibiotics and cycloheximide. In noncontaminated samples, the use of brain-heart infusion agar plus blood and antibiotics (without cycloheximide), a hemoglobin-containing agar incubated at 37°C, or both also is advisable. Cultures should be observed for 4 to 6 weeks, depending on temperature of incubation, with a definitive classification being accomplished only in the yeast phase.[37,110,155] The isolation rate of the fungus in culture varies from 80 to 100 percent but may be less in other nonspecialized centers.[37,110] As the mycelial form is not characteristic, subcultures in brain-heart infusion plus blood, Fava Netto agar, or peptone–yeast extract–glucose agar, for up to 14 days at 35°C to 37°C (95°F to 98.6°F), allow yeast conversion to occur and definitive diagnosis to be established.[110]

Paracoccidioides complex includes several different cryptic species, as observed by phylogenetic studies using multilocus sequence typing,[130] microsatellite analysis,[131] and PRP8 intein sequencing.[220] Phylogenetic analyses with several nuclear encoding regions showed a significant genetic distance between Pb01 and the remaining genetic groups.[130,131] More recently, the use of at least three single-nucleotide polymorphisms (*GP43*, *ARF*, and PRP8 intein genes), but not morphologic criteria, distinguished among the four cryptic species of the genus *Paracoccidioides*.[222] Morphologic evaluation indicated that elongated conidia were observed exclusively in *P. lutzii* isolates, whereas all other species (S1, PS2, and PS3) were indistinguishable.[222] *P. lutzii* isolates presented longer conidia (length ranged from 2.17 to 22.89 µm, with 11.07 µm being the median value) than S1 and PS2 conidia, whose lengths ranged from 2.25 to 7.99 µm (median value, 5.13 µm). Therefore, conidial morphology appears to be an important morphologic marker for differentiation between *P. lutzii* and the three cryptic species of the *P. brasiliensis* complex (S1, PS2, and PS3).[222]

Several sequences of *P. brasiliensis* DNA are of use in the identification of the fungus,* as is the exoantigen test with specific antiserum, mainly for atypical isolates.[107] The species-specific gp43 gene of *P. brasiliensis* was detected by loop-mediated isothermal amplification (LAMP) in DNA from *P. brasiliensis* strains in 3 hours, suggesting that this method may be applied to rapid identification of this fungus.[79,216] Recently, the identity of the *P. brasiliensis* typical and atypical strains could be confirmed by its dimorphism, by the expression of gp43, and by PCR using specific primers for gp43 as well as ribosomal internal transcribed spacer regions.[34,58,175] However, an important note is that one sequence (483 bp) of the *Lacazia loboi* gp43-like gene had 85 percent identity at the nucleotide level and 75 percent identity with the deduced amino acid sequences of the *P. brasiliensis* gp43 protein.[233]

Several *Paracoccidioides* spp. DNA sequences (Tables 201-3 and 201-4) of potential diagnostic use have been reported,† but few have been applied to clinical samples; further study is needed before they are introduced in diagnosis.‡ *Paracoccidioides* spp. DNA sequences of potential diagnostic use are species-specific sequences of the gene encoding gp43.[27,93,190,216] A PCR assay based on sequence of the gene coding for the gp43 antigen presented the highest sensitivity and specificity and gave a single band of 600 bp in sputum from a patient with chronic paracoccidioidomycosis.[93] Morais and colleagues[146] showed that some sequences of gp43 could undergo substitutions and need further testing to verify their universality and specificity for *P. brasiliensis*. The species-specific gp43 gene of *P. brasiliensis* was detected by LAMP in DNA extracted from a paraffin-embedded

tissue sample of paracoccidioidomycosis, suggesting that this method may achieve clinical application.[79,216] Work employing sensitive nested PCR,[27] the LAMP method of greater sensitivity, has been used[79] and detected the gp43 gene with a combination of F3, B3, FIP, and BIP primers designed from the partial sequence of gp43.[216]

P. brasiliensis strain genotyping was carried out directly from the paraffin-embedded tissue samples by modification of the diagnostic nested PCR assay.[190] Other approaches have been developed, such as MG2(1)F and MG2(1) primers that produced positive identification bands,[198] mainly in sputum samples. Further experience will be necessary to include molecular tests in routine diagnosis. Real-time PCR was developed for the detection of *P. brasiliensis* DNA in both culture and patients' clinical samples, and this procedure proved to be reproducible and specific.[40] Semi-nested PCR, with the primers ITS1 and ITS4 and MJ03 and ITS1, respectively, first and in the second reaction, was used to investigate biopsy specimens of five patients with oral lesions that resembled paracoccidioidomycosis. The test result was positive for four samples and negative for a sample from a patient later diagnosed with leishmaniasis.[109]

Patients with paracoccidioidomycosis not only have a polyclonal B-cell activation but also produce large amounts of anti–*P. brasiliensis* antibodies, which are long-lasting and generally correlate with the severity of the disease.* Assessment of the serologic response has long been used in paracoccidioidomycosis. It has been used as a diagnostic tool mainly because in a significant proportion of the patients, it is difficult to obtain clinical specimens for visualization or cultivation of the fungus when only deep-seated lesions are present. On some occasions, a serologic result is the first indication of the mycotic nature of the patient's illness. In recent years, a great interest has been generated in the development of techniques to improve paracoccidioidomycosis diagnosis. These developments have come in the fields of either antibody or antigen detection. Thus, serologic tests are of value for the diagnosis and may be useful in

monitoring the evolution of the disease and its response to treatment. Antibodies are encountered in patients with clinical symptoms, and generally the titers of antibodies can be related to the severity of the disease. Patients with paracoccidioidomycosis have a polyclonal activation of the humoral system with high serum concentrations of specific IgA, IgG, and IgE isotypes.* However, antibodies usually are impaired or absent in some patients with severe juvenile forms and in immunocompromised individuals.[69,232] On occasion, titer fluctuations may produce values below the level of detection by current methods, which may cause false-negative results. Experience over the years has resulted in various highly sensitive and widely employed serologic tests; the frequency of positive test results in patients with paracoccidioidomycosis varies from 70 to 95 percent and may even reach 100 percent in particular cases, depending on the type of test used and the stage of the disease. Of note is that discrepancies between serologic tests performed in different laboratories represent a problem because of the variation in reagents used, laboratory procedures adopted, and varying criteria for evaluation of the results obtained. Some of the most critical reasons for discrepancies are variations in the type of antigenic preparations, different strains, and, indeed, the mycelial or yeast cell phase chosen. Culture filtrates, cytoplasmic extracts, and antigens derived from the cell wall have been used as reagents in serologic tests for paracoccidioidomycosis, although culture filtrates are used in most laboratories.†

Remarkably, exoantigens from two *P. brasiliensis* strains isolated in two different geographic areas presented different results in immunodiffusion tests. When Ag 550B was used in an immunodiffusion test against sera of patients from Mato Grosso and São Paulo, positivity was 92.3 percent and 41.3 percent, respectively. On the other hand, when Ag B-339 was tested with the same sera, positivity was 26.2 percent and 100 percent, respectively. These results suggest that differences in the antigenic composition probably related to phylogenetic peculiarities in *P. brasiliensis* isolates from the central-western region of Brazil should be considered in the diagnosis of paracoccidioidomycosis.[15]

Various fractions that have been cloned, sequenced, and applied to the diagnosis include HSP60,[60] gp43,[175,225] gp70,[67] 27-kDa fractions,[57,162] P2,[42] combinations of the previously described 27-kDa recombinant antigen and the 87-kDa heat shock protein,[75] and rPb27 and anti-rPb40 antibodies, which showed a sensitivity of 96 percent with a specificity of 100 percent in relation to control normal human sera and to sera from patients with other systemic mycosis and 93.5 percent to sera from patients with diverse infections.[82] The main diagnostic antigen of paracoccidioidomycosis is the 43-kDa glycoprotein[175,225] because 100 percent of these patients' sera display antibodies against it, depending on the test.[45,138] This fraction has been extensively and successfully employed as an antigen in establishing the serologic diagnosis of paracoccidioidomycosis.

Many serologic tests have been developed and extensively studied. Agar gel immunodiffusion, complement fixation, and counterimmunoelectrophoresis tests have been employed extensively.[139] Complement fixation tends to be used less often because it is a difficult and time-consuming technique. Also available are indirect immunofluorescence, indirect hemagglutination, enzyme-linked immunosorbent assay (ELISA), and dot-blot immunobinding and immunoblotting.[139,214] Some of the newer tests have employed purified antigens, such as glycoprotein 43, which are well characterized and more specific.[175] Immunodiffusion and counterimmunoelectrophoresis, which employ crude antigens derived from the yeast phase, can detect 90 percent or more of active cases.[65] Most authorities recommend the use of two different tests because none of these tests guarantees more than 90 percent sensitivity when it is employed alone. Immunodiffusion, for instance, is simple and specific. Three precipitin bands, two of which are specific for *P. brasiliensis*, have been identified.[26,37]

A joint effort of several diagnostic centers assessing the value of this test with use of a reference crude antigen (Ag7) demonstrated it to be 84.3 percent sensitive and 98.9 percent specific[231]; but 15 percent represented false-negative results and constituted a failure of this diagnostic test, or they may be related to the production of low-avidity IgG2 antibodies directed against carbohydrate epitopes.[65] Patients with localized, benign disease may have negative results in these tests, but with more sensitive techniques (e.g., immunoblotting or gp43-ELISA), a diagnosis usually is reached. In our laboratory, three tests (immunodiffusion, counterimmunoelectrophoresis, and immunoblotting) are used in a routine serologic diagnosis. The sensitivities of these tests were 85.3 percent, 92.9 percent, and 100.0 percent, respectively, evaluated against 120 paracoccidioidomycosis sera (data not published). Other studies have also described Western blot analysis as a more sensitive test.[78,172] Limitations of these tests include cross reactivity to other mycotic disorders, especially histoplasmosis and *L. loboi* antigens, mainly in more sensitive tests,[175] and difficulties in standardization of the various tests and reagents.[44] The gp43 cross reactivities were predominantly attributed to periodate-sensitive carbohydrate epitopes containing galactosyl.[175]

The value of serologic tests in the follow-up of patients undergoing treatment also has been addressed by several centers.[136] The value of these tests in monitoring patients also is problematic, partly because of the diversity and complexity of the humoral response in patients with paracoccidioidomycosis. Serial serologic evaluations, usually done 3 months apart, together with the clinical, mycologic, and radiologic surveys can guide the treatment schedule, and two negative results in two of the serologic tests routinely employed is an additional criterion that helps in the difficult decision of therapy discontinuation.[139,207] The immunodiffusion, complement fixation, counterimmunoelectrophoresis, and ELISA tests were shown to be able to document the decline in antibody levels that parallels the clinical improvement; serum antibodies are cleared 1 to 2 years after cessation of therapy, depending on the clinical form.[38,70,139] Conversely, in

*References 8, 26, 29, 115, 138, 237.
†References 15, 44, 65, 70, 104, 139.

these circumstances, rising antibody levels indicate a relapse. Nonetheless, a considerable number of patients maintain, sometimes lifelong, the so-called healing titers (i.e., the persistence of low serologic titers in the tests). This is seen more frequently in patients with the acute form or the chronic multifocal form of the disease.[70] The debate on the clinical relevance of this phenomenon—whether it represents the persistence of residual active lesions, thus predicting possible future relapses—is inconclusive. During treatment of paracoccidioidomycosis, an important consideration is to be able to establish cure or remission criteria. A significant fall in reactivity of anti-gp43 antibodies has been shown to correlate with clinical improvement. During relapses, the levels of specific antibodies rose, and some patients considered cured exhibited a residual reactivity. Some patients have a negative immunodiffusion and counterimmunoelectrophoresis test result but a residual reactivity with gp43 and gp70 by immunoblotting.[37,70,75,138]

On the other hand, gp43 and gp70 can be detected in the biologic fluids. Furthermore, several studies have shown that the detection of antigens in blood and urine instead of antibodies is a potent means of establishing a diagnosis, monitoring treatment, and maintaining cure control.* They allow a more precise diagnosis to be established for patients with disseminated childhood and adult multifocal disease, in which antibodies are undetectable because of their coupling to excess antigen or the incapacity to raise antibodies. Antigenemia follow-up studies permit a more precise determination of improvement as antigen load decreases with treatment response. The detection of circulating antigen may represent a more practical approach to the early and rapid diagnosis of the disease.[63] It also will be helpful in establishing the diagnosis of immunocompromised patients, especially those with acquired immunodeficiency syndrome (AIDS), in which searching for an antibody response is not a completely reliable diagnostic tool.

The skin test with paracoccidioidin is not considered a diagnostic test because 30 to 50 percent of the patients prove nonreactive when they are tested initially.[26,29,56,86] Conversely, a positive skin test result indicates previous contact with the fungus but not necessarily active disease. When histoplasmin skin test material is used, cross reactions have been verified.[26,86] When the result of the skin test with paracoccidioidin is negative and the patient is treated, the skin test result may become positive, in which case the patient's prognosis is considered good.[37,110,155,184]

TREATMENT

The treatment of paracoccidioidomycosis is usually divided into two phases: acute and maintenance.[203] Two different drugs can be used for each phase, or the same drug can be used for the two phases but at different dosages. Among the reasons for this two-phase prolonged treatment are the chronic progressive nature of the disease and the knowledge that all currently available drugs, albeit with apparently different efficacies, are only fungistatic. Thus, an adequate humoral and cellular immune response is required to control the mycosis. Cellular immunity, however, may be impaired in a large number of patients because of malnutrition or the disease process itself.[11,24,150] Providing supportive therapy, therefore, is important. Rest, adequate nutrition, correction of anemia, and treatment of other concomitant infections are recommended.[136] Paracoccidioidomycosis is the only fungal disease that can be treated successfully with sulfa drugs. In children, sulfadiazine can be provided orally at daily doses of 60 to 100 mg/kg divided into four to six equal parts; in adults, a maximum daily dose of 6 g can be used. Water intake and urine alkalinization (usually by bicarbonated water intake) should be encouraged during therapy to prevent crystalluria and tubular deposits of sulfadiazine.[136,204] Duration of the acute treatment is dictated by the patient's response after clinical and serologic improvements have been attained; in general, in the chronic form, at least 6 months is required. A slow-acting sulfa drug (sulfamethoxypyridazine or sulfadimethoxine) can be provided as maintenance treatment, at a maximum daily dosage of 1 g. Resistance to sulfonamides has already been documented.[184]

In children, the precise total duration of therapy is variable according to the severity of the disease and as such should also be dictated by the clinical and serologic responses of the patient to treatment. The importance of continuous treatment must be emphasized because relapses occur if the drug is not taken regularly. Sulfonamides can be used by patients with mild or moderately severe disease. They also can be used for patients who have been treated initially with amphotericin B.[136] Brazilian physicians most often employ trimethoprim-sulfamethoxazole (80 mg of trimethoprim and 400 mg of sulfamethoxazole per tablet) given at a dose of two tablets and administered orally at 12-hour intervals with satisfactory results. This drug is also used in association with amphotericin B. Tolerability is good; myelotoxicity (leukopenia) is the main side effect, which can be monitored and controlled by folinic acid administration without modification of the therapeutic regimen. In general, children should be given half the dose given to adults.[11,136] A Brazilian consensus on paracoccidioidomycosis recommends 8 to 10 mg/kg of trimethoprim daily.[207] This combination has the advantage of permitting alternative parenteral administration whenever necessary. Duration of the acute treatment with this drug varies in each case, but it usually lasts for 6 months. Maintenance treatment in these cases can be achieved by using half the dose of the acute treatment or by using a slow-acting sulfa. Development of resistance to trimethoprim-sulfamethoxazole is occasionally clinically suspected but has rarely been documented in vitro. There is a single report of resistance of an isolate from an adult patient with the subacute form.[98]

Amphotericin B is effective but should be reserved for severely disseminated cases.[24,136] It also can be used by patients who relapse during the course of or after treatment with sulfonamide or any orally administered drug because gastrointestinal involvement may impair drug absorption in these cases. The effectiveness of therapy

*References 94, 118, 120, 137, 197, 231.

with azoles has curtailed the need for more aggressive regimens. More than one course of therapy may be required in some patients.

Some investigators have suggested the use of a combined amphotericin B–sulfonamide treatment. In adults, a total cumulative dose of amphotericin B of 1 to 2 g followed by sulfa drugs, given as indicated previously, usually is sufficient.[123] With this drug combination, clinical improvement can be achieved in about 75 percent of patients; about 10 percent do not respond as well, and the remainder die during treatment. Relapses may be expected in about 10 to 15 percent of optimally treated patients.[138] Data about effectiveness of the new amphotericin B lipid formulations in paracoccidioidomycosis are still required.[73]

Ketoconazole is rarely considered the therapy of choice because of its side effects and numerous drug interactions compared with other triazole derivatives for oral administration (itraconazole, fluconazole). Today, more experience has been gained with itraconazole.[136,154,157,169] This triazole is more potent and less toxic than ketoconazole and is equally effective as or even more effective than the parent compound. It is administered in 100-mg capsules that should be given with or shortly after a meal. One or two capsules, depending on the severity of the fungal process, taken daily for 6 months have been shown to be effective in reducing all active lesions. Most (98%) of the patients, including children and young adults, respond.[136,154] Post-therapy observations indicate variable proportions (ranging from 2.1% to 21%) of relapses, depending on the severity of the disease, duration of therapy, and time of follow-up.[122,223] Side effects have been few and include transient elevation of hepatic enzymes.[136,154,223] At present, several well-conducted (but noncomparative) trials have been reported favoring this triazole, which has become the first choice for the treatment of paracoccidioidomycosis in many reference centers. The experience in treating childhood paracoccidioidomycosis with itraconazole still is limited compared with that with amphotericin B and trimethoprim-sulfamethoxazole, but the few reports are encouraging.[157,169] A randomized trial with sulfadiazine, ketoconazole, and itraconazole for the treatment of adult patients with disease of moderate severity failed to show higher efficacy of a particular regimen over the others.[204] However, long-term follow-up was not evaluated in this study. Itraconazole maintenance therapy is recommended at a dose of 5 to 10 mg/kg daily, with a maximum dosage of 200 mg twice daily. A liquid formulation of itraconazole in cyclodextrin was initially suggested as a promising alternative for treatment of children, but it has not been marketed in countries where the disease is endemic, and thus far no clinical experience could be gathered to support its recommendation.

Fluconazole is not as effective in this disorder; higher doses, up to 600 mg/day, and longer treatment periods are required. Recrudescence and relapse of disease occur more frequently than when itraconazole is used.[24,136] Fluconazole may be useful in severely ill patients who must be treated intravenously.[136] No experience in children is available. The literature has only one report of the successful use of terbinafine in an adult patient.[160] Voriconazole is an extended-spectrum triazole antifungal agent that is available in both oral and intravenous formulations. In vitro susceptibility data show that *P. brasiliensis* is highly sensitive to voriconazole. A pilot open label study showed that it is well tolerated and as effective as itraconazole for treatment of chronic paracoccidioidomycosis.[179] However, this drug has not yet been approved for pediatric use.

Many questions remain to be answered about optimal treatment of paracoccidioidomycosis. The role of adjunct therapy with immunomodulators, such as peptides derived from the immunodominant glycoprotein of *P. brasiliensis* that act by augmenting the Th1-mediated immune responses, has been investigated mainly in experimental models of the disease and showed promising results.[226] Two studies demonstrated some reactivity of patients' T cells to these peptides.[103,195] Further studies are required to demonstrate their utility in promoting protective cell-mediated immune responses in the human host. α-Glucan obtained from *Saccharomyces cerevisiae* with immunoenhancing properties has been preliminarily investigated, but further studies are also needed.[134] In the opposite direction, some investigators have administrated short courses of corticosteroids as adjunct therapy in severe cases on the basis of the rationale that the failure to improve with antifungal therapy observed in these cases was due to uncontrolled or excessive inflammatory response.[17,97] Some fatalities were attributed to the exacerbated inflammatory response.[18,25] The clinical and laboratory criteria that allow the transition from the attack to the maintenance treatment phases have not been standardized, nor have the parameters that could be used to end treatment with the assurance that the patient is cured. Progressive decrease in the titers of the serologic tests currently available is one of the laboratory parameters used most frequently. Newer methods (e.g., antigenemia detection and molecular biology approaches) still need further standardization and clinical studies and have not yet become widely available.[94,118,121] Meanwhile, most specialists agree that treatment decisions need to be tailored according to the patient.

PROGNOSIS

Paracoccidioidomycosis has no prophylaxis. Vaccine strategies are being developed but are still restricted to experimental models of the disease.[226] The mycosis can be fatal if it is left untreated, but currently this has seldom been observed.[18,25,171] On the other hand, sequelae still remain a problem. Residual lesions have been observed in a few patients with no known history of active mycotic infection.[87,90,135] Prognosis depends on the status of the patient at the time of diagnosis. Children and young adults in whom fungemia has taken place and who have multiple organ involvement may respond less well to therapy. The fatality rate in young patients at one time was reported to be 31 percent,[51] but it now is much lower as a result of earlier diagnoses and better treatments. Nevertheless, it remains a life-threatening disease with 9.5 to 13 percent fatalities in the most recent series. This was attributed to delayed diagnosis or searching for

medical assistance, irregular treatment, or treatment not monitored. Abdominal complications, especially ascites and malnutrition, were associated with the lethal prognosis.[11,157,169] In the adult group, mortality rates are much lower. Once specific treatment is instituted, lesions regress promptly; skin lesions may heal completely in 2 to 4 weeks.[136] Complete remission is expected for most patients with the acute-subacute and chronic form of the disease. Prognosis has improved as a result of earlier diagnosis and new antifungal drugs that facilitate compliance; better knowledge of the disease has provided better clinical and laboratory follow-up and the notion that the disease needs prolonged surveillance, as shown by the decrease in positive mycologic test results during and after therapy.[136,223] Some investigators consider the term *cure* inappropriate because of the inability to confirm complete eradication of the organism; the term *apparent cure* should instead be used.[136]

Paracoccidioidomycosis persists as a disease with low mortality but high morbidity. Complications vary and, like prognosis, their occurrence depends on the extent of fungal invasion. In the juvenile form, early complications that may lead to surgical intervention are intestinal obstruction and jaundice, both of which result from enlarged mesenteric lymph nodes. Disabsorptive syndromes may be associated, aggravating the nutritional status of the patients.[20,206] Patients also may present with ascites or chylothorax. Lymph nodes may suppurate, and fistulas can develop. A late complication that has been described is abdominal malakoplakia.[194] In the adult form, acute complications of mucosal involvement are dysphagia and dysphonia,[235] edema of the glottis, respiratory insufficiency, and Addison disease, among others. Sequelae are not as common in children as in adults. In general, fibrosis is the cause of serious problems in patients who respond to therapy. Despite the newer, effective therapies, these sequelae preclude, in a proportion of the cases, the complete restoration of the patient's previous health status.[135,136,154,223] In the former group, scarring and fibrosis of the affected nodes and residual pulmonary fibrosis have been noted.[114] Malabsorption syndrome probably is the most serious sequela in the juvenile form because of the enteric loss of proteins and inflammatory cells that results in immunodeficiency and opportunistic infections.[20,206]

Acknowledgments

We would like to deeply acknowledge Prof. Angela Restrepo for her invaluable contribution to this version of the chapter and Drs. Maria Gorete Nogueira and Ricardo Pereira for their comments and sharing of unpublished material. In addition, we would like to thank Irani Coito for the bibliography revision.

CHAPTER 202

Cryptococcosis

David Goldman • John Perfect

Cryptococcus neoformans is an encapsulated yeast that causes meningoencephalitis and pneumonia in both immunocompetent and immunocompromised children. Since its identification as a pathogen in 1894,[103] great strides have been made in our understanding of the biology and the pathogenesis of cryptococcosis. The incidence of cryptococcosis has greatly increased in association with the acquired immunodeficiency syndrome (AIDS) epidemic and improvements in health care, which have resulted in an increased number of individuals at risk

for cryptococcosis. We have also come to recognize *C. neoformans* comprises at least two separate species, *C. neoformans* and *C. gattii*, that evolved from each other more than 40 million years ago.[33] Disease caused by these two species is similar in many ways, but there are important differences. An outbreak of *C. gattii* disease in the Pacific Northwest was first identified in the late 1990s beginning on Vancouver Island. Despite the availability of antifungal therapy, the mortality associated with cryptococcosis remains high and new therapies and prevention strategies are needed.

THE ORGANISM

C. neoformans is an encapsulated basidiomycete that is evolutionarily distinct from yeasts like *Candida albicans* and more closely related to corn and grain plant fungal pathogens.[63] *C. neoformans* is a round yeast (5 to 10 μm diameter) that produces white (frequently mucoid) colonies on standard mycologic media. The capsule varies greatly in size depending on the local milieu. Recently, giant cells (80 to 100 μm diameter) called titan cells have been described in animal studies, although the clinical significance of these forms remains to be understood.[46] *C. neoformans* is capable of sexual reproduction in the laboratory, and mating types (alpha and A) have been identified. In the environment and during infection, the organism is typically haploid and replicates asexually. *C. neoformans* was originally classified into five serotypes (A, B, C, D, and AD) based on its reaction with anticapsular serum. Serotypes B and C, formally known as *C. neoformans* var. *gattii* are now collectively named *C. gattii*. Serotype A (classified as *C. neoformans* var. *grubii*) is responsible for the vast majority of *C. neoformans* disease. Serotype D (*C. neoformans* var. *neoformans*) is primarily found in Europe and occasionally hybrids such as serotype A/D and other diploid strains are found in nature. *C. neoformans* and *C. gattii* can be distinguished by a variety of biochemical, serologic, and molecular typing techniques, although these are not routinely available in clinical microbiology laboratories. For instance, *C. gattii* (but not *C. neoformans*) produces blue coloration on L-canavanine-glycine-bromothymol blue (CGB) medium. The advent of molecular typing techniques has further enhanced our understanding of cryptococcal pathogenesis. With the use of these techniques, both *C. neoformans* and *C. gattii* can each be classified into four molecular types: VN I to IV and VG I to IV, respectively, with further subtypes. Future work may actually divide these into separate species. Other species of *Cryptococcus* (e.g., *Cryptococcus laurentii*, *Cryptococcus albidus*) are less virulent and rarely have been reported to cause disease.[11,47]

Virulence

Several important virulence traits common to *C. neoformans* and *C. gattii* include encapsulation, melanization, the ability to grow at 37°C, and both urease and phospholipase production. These characteristics are not uniformly present in other cryptococcal species. The emergence of some of these traits has been hypothesized to have been selected for because of survival advantages they confer in their natural environment, where these yeasts are exposed to invertebrate predatory scavengers such as worms and amebae.

Capsule

The impressive capsules of *C. neoformans* and *C. gattii* are composed of long unbranched polymers of xylose and glucuronic acid. The capsule plays a central role in cryptococcal virulence, and acapsular/hypocapsular mutants exhibit greatly reduced virulence.[19] Although capsules can be produced by other cryptococcal species, studies suggest that there are important differences in the biophysical properties between the capsule of virulent and nonvirulent species.[7] Capsule size is actively regulated in response to local conditions such as pCO_2, serum, and iron. In nature, the capsule likely protects the yeast from desiccation and ingestion by soil amebae. The capsule gives the organism its distinctive appearance in India ink staining (Fig. 202-1). The substantial polysaccharide material forming the capsule is extensively shed into host tissue, cerebrospinal fluid (CSF), and serum during infection; and the detection of this polysaccharide forms the basis of cryptococcal antigen testing. Similar to prototypical pediatric pathogens (e.g., *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Neisseria meningitidis*), the cryptococcal capsule inhibits antibody- and complement-mediated phagocytosis and thereby interferes with the development of an effective immune response.[77] However, the capsule also exhibits a variety of other anti-inflammatory properties, including inhibition of leukocyte migration,[37] enhanced interleukin-10 secretion,[145] inhibition of T-cell proliferation,[153] and induction of macrophage apoptosis.[149] In addition, the cryptococcal capsule also has been hypothesized to contribute to cerebral edema[59] and to promote replication of the human immunodeficiency virus (HIV).[120] Given the central role of the capsule in cryptococcal pathogenesis, administration of capsular-specific antibody has been studied as potential adjunctive therapy in animal models.[104,126] However, this therapeutic approach has so far had limited success in humans.[81]

Melanin

Melanin is a pigment that is synthesized from catechol precursors (e.g., dopamine, epinephrine) by the laccase enzymes of *C. neoformans* and *C. gattii*. The laccase enzyme is similar to enzymes produced by wood-rotting fungi and is capable of digesting lignin, an important constituent of trees, and may thereby promote growth of the yeast in decaying trees. Melanin is produced during cryptococcal infection and is localized to the cell wall.[123] Melanin content can vary significantly among *C. neoformans* strains.[151] Yeast mutants lacking the ability to produce melanin are less virulent in animal models than their melanin-producing parental strains. Although melanin structure remains poorly understood, its chemistry endows it with the ability to stabilize free radicals and provides a stable framework even under extremely harsh environmental conditions. These characteristics

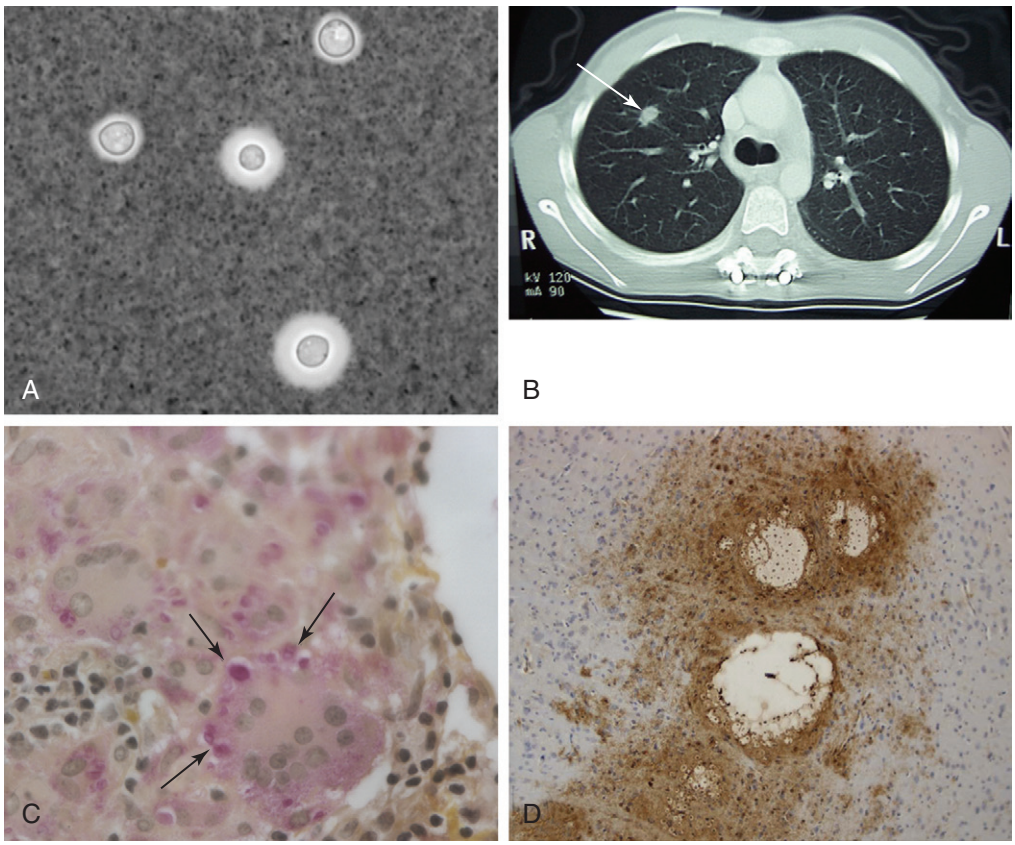

FIGURE 202-1 ■ **A,** India ink staining of CSF demonstrates *C. neoformans* and capsule, which excludes the stain and results in a halo around the organism. **B,** CT scan of child with rhabdomyosarcoma reveals nodule (white arrow) secondary to *C. neoformans*. **C,** Mucicarmine staining of a lung from a rat with experimentally-induced pulmonary cryptococcosis shows granulomas containing *C. neoformans* (black arrows). **D,** Immunostaining for cryptococccal polysaccharide reveals extensive shedding of polysaccharide within the brain parencyhma and around cryptococcomas of a rat with experimentally induced cryptococcal meningoencephalitis. (See Expert Consult website for color version.)

likely play an important role in the capacity of melanin to protect against damage caused by nitrogen- and oxygen-derived host oxidants in addition to exogenous factors such as ultraviolet light and antifungal agents. Melanin also appears to promote disease through its immunomodulatory properties[62] and its ability to bind to host antimicrobial peptides.[107] One explanation for cryptococcal neurotropism relates to the hypothesis that high concentrations of catechol precursors within the brain promote cryptococcal melanization, which in turn protects the organism from the host immune response within the brain.[121]

Extracellular Enzymes

C. neoformans and *C. gattii* also produce a variety of extracellular enzymes that have been linked to virulence, including proteinase, phospholipase, and urease. Urease catalyzes the hydrolysis of urea to ammonia and carbamate. The importance of urease in virulence and during infection appears to depend on the infection site and may be more important for pulmonary infection than brain infection.[31] Urease production by *C. neoformans* has been associated with the accumulation of immature dendritic cells and the production of a disease-enhancing T-helper cell type 2 (Th2) inflammation.[110] *C. neoformans* strains vary in their phospholipase production, and high phospholipase production has been associated with increase fungal burden in animal models.[147] Conversely, lack of phospholipase production has been linked to reduced virulence. Phospholipases have also been implicated in promoting entry into the brain[30] by promoting passage through brain endothelial cells.[96] Phospholipases may also promote intracellular growth by releasing arachidonic acid from host cells.[152]

Other virulence factors that have been identified, include mating type,[79] prostaglandin production,[42] and phenotypic switching.[48] The calcineurin signaling pathway has been implicated in induction of metabolic and oxidative stress genes in response to environmental stimuli. This pathway appears to play a role in promoting survival both within the environment and host.[109]

ECOLOGY AND EPIDEMIOLOGY

Cryptococcus neoformans

There are important differences in the ecology of *C. neoformans* and *C. gattii* (Table 202-1). *C. neoformans* (but not *C. gattii*) is well known for its association with bird droppings, including those from pigeons, canaries, and

TABLE 202-1 **Summary of Characteristics of *Cryptococcus gattii* and *Cryptococcus neoformans***

	Cryptococcus gattii	*Cryptococcus neoformans*
Microbiology	Serotypes B and C Molecular type VGI associated with Australia and VGIIa with outbreak in Pacific Northwest Bluish discoloration on CGB media	Serotypes A and D Molecular type VNI most common cause of *C. neoformans* diseases
Ecology	Eucalyptus and other trees	Bird droppings and trees
Epidemiology	Immunocompetent > Immunocompromised Endemic in certain tropical/subtropical regions Outbreak in Pacific Northwest	Immunocompromised (especially AIDS and T cell defects) > Immunocompetent High incidence in sub-Saharan Africa and Southeast Asia Decreased incidence in regions where HAART is available
Clinical Manifestations	Primary pulmonary infection and CNS cryptococcomas with associated complications	Meningoencephalitis and disseminated disease a common presentation, especially among AIDS patients

parrots. *C. neoformans* is capable of growth in the acidic environment of bird droppings. Nonetheless, birds are unlikely to be the primary environmental source for *C. neoformans* because their high internal temperatures inhibit *C. neoformans* growth and possibly possess innate avian host factors against this yeast. In addition, the *C. neoformans* density is much higher in aged pigeon droppings compared with fresh droppings, suggesting the possibility for secondary contamination as the mechanism for this ecologic niche.[91] Other noted environmental sources for *C. neoformans* include rotting trees and fruits.[26,92]

There are also important differences in the epidemiology of disease caused by these different species of cryptococcus. *C. neoformans* is generally considered an opportunistic pathogen that causes central nervous system (CNS) and respiratory disease in patients with depressed cellular immunity. However, cryptococcosis secondary to *C. neoformans* also occurs in individuals without any identified risk factors. A dramatic increase in the prevalence of cryptococcosis occurred in association with the AIDS epidemic. In patients with HIV infection, cryptococcal meningoencephalitis is an AIDS-defining diagnosis, typically occurring in both adults and children with profound immunodeficiency, as evidenced by a finding of $CD4^+$ T cells less than 100/μL. In countries where highly active antiretroviral therapy (HAART) has been successfully introduced, the prevalence of cryptococcosis has greatly decreased. Unfortunately, cryptococcosis has emerged as a significant cause of disease in AIDS patients in countries with limited resources. Worldwide, most cases of cryptococcosis occur in sub-Saharan Africa and Southeast Asia, affecting an estimated 1 million individuals annually[115] and up to 30 percent of AIDS patients.[12] In South Africa, *C. neoformans* is the leading cause of meningitis in adults, with an incidence more than twice that of tuberculous meningitis.[68] In developed countries, an increase in the incidence of *C. neoformans* disease among non–HIV-infected individuals has been recognized. This appears to be primarily associated with improvements in medical care and an increase in the number of individuals receiving immunosuppressive therapy, especially organ transplant recipients. Among solid-organ transplant recipients, cryptococcosis is the third most common invasive fungal infection. Among non–HIV-infected patients with cryptococcosis in the United States, 20 to 60 percent are transplant recipients.[148]

Overall, cryptococcosis secondary to *C. neoformans* is less common in children than adults but remains an important cause of pneumonia and meningoencephalitis, especially in certain parts of the world. Owing to the rarity of pediatric cryptococcosis, the precise prevalence is difficult to define and may vary by region. Studies of U.S. children with AIDS in the 1990s estimated an incidence of cryptococcosis to be about 1 percent.[50] A more recent U.S. series identified 63 cases of pediatric cryptococcosis from a consortium of 42 children's hospitals over a 5-year period, with an admission rate of 6.2 per million hospitalizations.[70] Most children (63.5%) in this cohort had underlying immunosuppression, whereas 21 percent were immunocompetent and 16 percent had AIDS. The 8-year point prevalence of cryptococcosis among Thai children with AIDS was 2.97 percent.[89] A study from South Africa reported 361 cases of pediatric cryptococcosis over a 3-year period, comprising 2 percent of all cases of cryptococcosis over this time.[99] The reported median age at time of diagnosis of pediatric cryptococcosis varies from 7 to 12 years. In most series, pediatric cryptococcosis rarely occurs in children younger than age 1 year, although in the South African cohort an increased incidence was noted within the first year of life. In addition to AIDS, cryptococcosis has been identified in children with a variety of primary and secondary immunodeficiency states, including organ transplantation, lymphoma, leukemia, lupus, glucocorticoid therapy, sarcoma, hyper-IgM syndrome, Bruton agammaglobulinemia, and severe combined immunodeficiency.[4,66,84,135,150] Neonatal cryptococcosis is rare but has been described (see later discussion).

Although the incidence of symptomatic cryptococcosis is disproportionately low in children, serologic studies suggest that children from certain regions of the country may be infected with *C. neoformans* at a very young age.[49]

The basis for this discrepancy between serologic findings and clinical disease is unknown. It is likely that most pediatric infections are asymptomatic or misdiagnosed as viral disease. Potential reasons for the low incidence of symptomatic pediatric cryptococcosis include the time needed to reactivate infection, the importance of repeated exposures, and differences in infecting strains.[101] Nonetheless, it remains a perplexing issue after serologic study as to why many children appear to be infected but rarely develop disease.

Cryptococcus gattii

In contrast to *C. neoformans*, *C. gattii* was initially recognized as a disease of tropical regions and endemic in Australasia, where it is associated with eucalyptus trees (both river red and forest red gum trees). However, recent studies have revealed that *C. gattii* causes disease in both tropical and temperate regions. This includes areas without eucalyptus trees, suggesting the possibility of other environmental reservoirs. In the Pacific Northwest, *C. gattii* has been isolated from non–eucalyptus tree species (Douglas fir, alder, and Garry oak), soil, air, fresh water, and sea water.

Cryptococcus gattii causes disease in both immunocompetent and immunocompromised individuals, although disease appears to be more common among immunocompetent individuals compared with *C. neoformans.* In an Australian study of *C. gattii* disease, 72 percent of patients had no recognizable immune deficit.[25] Some investigators, however, have hypothesized that affected individuals actually reported to be normal hosts have a subclinical immune deficit.[95] Because standard microbiologic techniques fail to distinguish between the two species, the precise prevalence of *C. gattii* disease is not known. Recently, *C. gattii* has been increasingly recognized to cause disease outside Australasia and tropical regions. Over the past 13 years, *C. gattii* has been linked to an outbreak of disease in the Pacific Northwest. This outbreak was initially recognized on Vancouver Island with subsequent extension into the United States (including the states of Washington and Oregon). In this outbreak, corticosteroid use and older age (>50 years) have been associated with increased severity.[56] Cryptococcosis secondary to *C. gattii* may occasionally occur in travelers returning from the Pacific Northwest. Disease typically presents within weeks to months after travel but may occur as long as a 1 year after travel.[55] There are also cases being reported outside the geographic boundaries typically associated with *C. gattii* disease.[97] This change in the environmental location of *C. gattii* may be the result of genetic changes in the yeast or climactic changes that allow the organism to successfully compete in new geographic regions.

The incidence of cryptococcosis secondary to *C. gattii* in children is not well characterized. Of 218 cases of cryptococcosis secondary to *C. gattii* in British Columbia between 1999 and 2007, 4 cases (1.8%) occurred in children younger than 18 years.[43] In contrast, among 43 cases of *C. gattii* meningoencephalitis in a series from Brazil, 19 percent were children younger than 12 years.[127]

PATHOGENESIS

C. neoformans and *C. gattii* infections are believed to be acquired through inhalation of infectious propagules within the environment. The precise infecting form remains to be understood and may involve either desiccated yeast cells or small basidiospores (1 to 2 μm), thus allowing alveolar deposition. Once within the lung, infection may cause disease through progression of pneumonia and dissemination to the CNS. Alternatively, infection may be contained in a dormant site within the lungs and reactivate in the setting of subsequent immunosuppression, such as HIV infection or corticosteroid use. Evidence for reactivation disease includes molecular typing[45] and pathologic[57] and serologic studies.[125] Furthermore, recent reports of very early cryptococcosis after organ transplantation highlight the tendency of *C. neoformans* to cause latent infections within transplanted organs.[137] Differences in the propensity for *C. neoformans* and *C. gattii* to cause primary progressive disease may exist. For example, molecular typing studies and cases of cryptococcosis among returning travelers to the Pacific Northwest highlight the potential for *C. gattii* to cause primary progressive disease.[15,18] These findings are consistent with findings from animal experimentation.[78] Within the lung, both innate and adaptive immune responses are essential to the effective control of infection. *C. neoformans* can be recognized by the cells of the innate immune system through a variety of receptors including, Toll-like, β-glucan, and mannose receptors. Macrophages play a central role in the host immune response.[129] Dendritic cells, natural killer cells, neutrophils, and activated macrophages can kill the yeast. *C. neoformans* is a facultative intracellular pathogen and is well adapted to survive and replicate within the acidic environment of the phagolysosome.[86] Unlike other intracellular pathogens, *C. neoformans* does not employ typical strategies to escape or modify the phagolysosomal compartment. However, intracellular survival within the harsh environment of the phagolysosome is supported by virulence traits, including capsule production, melanization, secretion of extracellular enzymes, and prostaglandin production. Interestingly, *C. neoformans* can escape the macrophage through induction of cell lysis or phagosomal extrusion.[5] The latter process allows the transfer of yeasts between macrophages without inducing macrophage death and associated inflammation. This novel mechanism likely promotes the intracellular persistence of *C. neoformans.*

Adaptive immunity and T-cell–mediated activation of macrophages is central to the effective host response. The importance of T-cell immunity in the protective host response to cryptococcosis is highlighted by the increased susceptibility of individuals with defective T-cell immunity to cryptococcosis. Animal experimentation highlights the protective nature of T-helper cell type 1 (Th1) immunity and nonprotective (disease-enhancing) nature of Th2 immunity.[60,73] In this regard, *C. neoformans* and *C. gattii* virulence has been linked to the ability to actively modulate the inflammatory response and to elicit nonprotective Th2 inflammation.[2,32]

PULMONARY CRYPTOCOCCOSIS

The lungs are the most commonly recognized body site of cryptococcal disease after the CNS. Pulmonary cryptococcosis can present as the primary manifestation of cryptococcosis (e.g., without extrapulmonary disease) or in association with disseminated disease/meningoencephalitis. Symptomatic pulmonary cryptococcosis typically occurs in individuals with underlying immunodeficiency or chronic lung disease. Nonetheless, pulmonary cryptococcosis in individuals without recognized risk factors is well described and appears to be more common for infection secondary to *C. gattii*. In one study of HIV-negative patients with cryptococcosis, 15 percent of patients with pulmonary cryptococcosis had no underlying disease.[114] Among AIDS patients with cryptococcal meningoencephalitis, pulmonary cryptococcosis has been reported to be present in a wide range (10% to 55%) of patients.[14] This variation may occur as a result of the nonspecific features of pulmonary disease along with differences in diagnostic evaluation.

Case reports and series describing adults with primary pulmonary cryptococcosis first appeared in the 1960s. Initial descriptions of this disorder highlighted the chronic, nonspecific nature of pulmonary cryptococcosis and a tendency for it to occur in older white men.[16] Although primary pulmonary cryptococcosis occurs in apparently normal hosts, several underlying conditions (in addition to HIV) have been identified as risk factors. These include corticosteroid use, chronic lung disease, Cushing syndrome, diabetes mellitus, malignancy, tuberculosis, rheumatologic disease, and chronic obstructive pulmonary disease.[5,114] Among patients with cancer, a lymphoid malignancy is present in the majority of patients with pulmonary cryptococcosis, as is corticosteroid usage and lymphopenia.[76] Reports highlight the risk for anti–tumor necrosis factor therapies and pulmonary cryptococcosis, similar to that for tuberculosis and other endemic mycosis.[54] In a multicenter study of organ transplant recipients, 39 percent of patients with cryptococcosis had primary pulmonary disease.[112] Primary pulmonary cryptococcosis has also been reported to be disproportionately more common in the British Columbia *C. gattii* outbreak, where it is the most common form of presentation.[44] Nonetheless, the presentation of *C. gattii* disease may still be primarily dependent on host immune status.[25]

Pulmonary Cryptococcosis in Children

Pulmonary disease as the primary manifestation of cryptococcosis in children is uncommon but has been described and affects both immunocompetent and immunocompromised children.[50,111] Infected children usually have chronic respiratory tract symptoms (i.e., cough, fever, chest pain, and weight loss) and are initially treated for bacterial pneumonia before the diagnosis is suspected. In one review of pulmonary cryptococcosis in children a predilection for lower lobe lung disease was apparent, with most children being asymptomatic, immunocompromised, and male.[140] Children may be asymptomatic and the diagnosis recognized as a result of imaging performed for other reasons. Several characteristic cases of pediatric pulmonary cryptococcosis in the context of soft tissue malignancy have been previously diagnosed as a result of imaging to evaluate for metastasis.[4,140] These children all had lung nodules that were initially thought to represent metastatic disease and were often lymphopenic.

Clinical Manifestations

The typical symptoms of symptomatic pulmonary cryptococcosis include cough, chest pain, dyspnea, fever, and weight loss.[16,74] Several studies indicate that a significant proportion of affected patients do not have respiratory symptoms. In a study of pulmonary cryptococcosis among solid-organ transplant recipients, 38 percent of the patients were asymptomatic.[131] Asymptomatic disease appears to be more common among immunocompetent individuals but does occur in immunosuppressed patients and may be initially confused with cancer. In patients with recognizable pulmonary disease, symptoms are typically mild and often chronic. In immunocompetent individuals, primary pulmonary cryptococcosis is often self-limited. In contrast, pulmonary cryptococcosis among immunocompromised individuals is more likely to occur in the context of disseminated disease or progress to involve the CNS. Constitutional signs, especially fever, weight loss, and anorexia, have been described, particularly in association with underlying immunosuppression. Rarely, pulmonary cryptococcosis can rapidly progress to acute respiratory distress syndrome. Coinfection with other pathogens, including *Mycobacterium tuberculosis* and *Aspergillus* spp. occasionally has been described.[41,144]

Radiology

The three most common radiologic appearances of pulmonary cryptococcosis are nodular (see Fig. 202-1), infiltrative, and interstitial, although pleural effusions and cavitary disease have also been described.[27,75] Nodules may be solitary or multiple and are nonspecific. Among AIDS patients, interstitial disease and large lobar infiltrates are the most common radiologic findings. Interstitial findings may be an indication of disseminated disease. Nodular densities or mass lesions are more likely to be asymptomatic or incidentally detected pulmonary cryptococcosis than pleural effusions and infiltrates.[131] Cavitation of cryptococcal nodules and infiltrates may occur especially in immunocompromised individuals and has been described in the context of immune reconstitution inflammatory syndrome (IRIS, see later discussion) in AIDS patients.[69]

Diagnosis

Sputum culture has an extremely limited sensitivity in the diagnosis of pulmonary cryptococcosis. In one study, only 19 of 101 cases of pulmonary cryptococcosis in adults were confirmed by sputum culture.[16] Bronchoscopy with fungal culture and antigen testing of lavage fluid may aid

in the diagnosis of cryptococcosis, although the sensitivity of this approach appears to be variable. Definitive diagnosis may require obtaining tissue through either transthoracic, transbronchial or open-lung biopsy. Serum cryptococcal antigen is typically nondetectable in isolated pulmonary cryptococcosis, and the presence of serum antigenemia supports consideration of disseminated disease.

CRYPTOCOCCAL MENINGOENCEPHALITIS

Cryptococcal meningoencephalitis typically involves the base of the brain and is usually associated with brain parenchymal involvement. Infection may extend through the Virchow-Robin space into the brain substance, most commonly affecting the midbrain and basal ganglia. Immunohistochemistry studies of brains from patients reveal extensive shedding of cryptococcal polysaccharide into the brain parenchyma (see Fig. 202-1).[82] Subarachnoid and parenchymal inflammation ranging from minimal to extensive granulomas may be present, depending on the host immune status and fungal burden.[83] Increased intracranial pressure (ICP) often complicates cryptococcal meningoencephalitis and contributes significantly to the morbidity and mortality of this disease. Cryptococcomas and CNS complications including hydrocephalus and cranial nerve palsies appear to be more common with *C. gattii* disease.[102,134] Differences between cryptococcal meningoencephalitis in HIV-infected and non–HIV-infected individuals have also been described. This includes a more acute presentation and the presence of a second site of infection in HIV-infected individuals.[87]

The mechanisms by which *C. neoformans* and *C. gattii* enter the CNS are not well understood. In general, organisms cross the blood-brain barrier by one of three mechanisms: transcellular, paracellular, or via infected phagocytes (Trojan horse). Evidence for both transcellular[20] and Trojan horse mechanisms exist for *Cryptococcus*. In this regard, *C. neoformans* adheres to and infects endothelial cells in vitro.[65] This process may be active and involve the secretion of enzymes (e.g., urease, phospholipase), which in turn induces cytoskeleton rearrangements, resulting in ingestion.[96] Evidence supporting the Trojan horse model comes from experiments in which CNS infection was successfully produced by infection of mice with *C. neoformans*–infected monocytes.[23]

Clinical Manifestations

Cryptococcal meningoencephalitis is a subacute to chronic process that generally presents symptomatically over weeks to even months. Occasionally, shorter and longer time intervals are described. Affected patients typically have a headache with or without a variety of other nonspecific symptoms, including fever, lethargy, nausea, and vomiting. Meningismus and photophobia, which are typical of bacterial meningitis, are often absent in adults. Symptoms of encephalitis may also be present and even predominate, including personality changes, memory loss, and altered mental status. Patients with cryptococcomas can have signs of increased ICP and localizing neurologic symptoms, consistent with an intracranial mass.

Pediatric Cryptococcal Meningoencephalitis

Because of the small number of cases, it is difficult to know if there are clinical differences in pediatric compared with adult meningoencephalitis. The most common symptoms reported in the largest pediatric series to date are headache and fever. Other commonly reported symptoms include nausea and vomiting. In one study of affected African children with AIDS, seizures were significantly more common in children when compared with adults (38% vs. 11%); however, this high incidence of seizures has not been reported in other pediatric series.[53] Additional reported symptoms include altered mental status, focal neurologic deficits, photophobia, abdominal pain, and respiratory symptoms. In some studies, meningismus is present in the majority of children. Like adults, it is common to see a lack of CSF inflammation in children with cryptococcal meningoencephalitis and CSF profiles may be relatively normal. Increased ICP in pediatric cryptococcal meningoencephalitis is well described, but the precise incidence is not well documented. In one study, more than 80 percent of children with cryptococcal meningoencephalitis had increased ICP.[89]

Diagnosis

Cerebrospinal Fluid Profile

The CSF profile of both adults and children with cryptococcal meningoencephalitis is characterized by a lack in both cellularity and alterations in biochemical profile, especially in HIV-infected individuals. In pediatric studies, mean CSF white blood cell counts vary from 4 to 16 cells/mm^3.[1,61,128] In another study, approximately 50 percent of infected children had normal CSF findings (with a normal white blood cell count of <7 cells/mm^3).[89] Likewise, CSF protein and glucose concentrations are often normal, although elevated protein concentrations may be present, especially with obstruction. In one study, decreased glucose or increased protein concentrations were present in 19 percent of infected children.[89] Given the normal appearance of CSF, a high suspicion and cryptococcal specific studies (see later discussion) are necessary for diagnosis.

Imaging

In cryptococcal meningoencephalitis, imaging often underrepresents the extent of disease, although magnetic resonance imaging results are more likely to be abnormal.[22] The presence of imaging abnormalities may be a marker of more extensive disease and high risk for death.[38] Meningeal enhancement is not uniformly present, which likely reflects the paucity of inflammation in this disease. In a study of solid-organ transplant recipients

with cryptococcal meningoencephalitis, meningeal enhancement (the most common finding) was present in only 15 percent of patients.[132] A similar frequency of enhancement has been reported in patients with AIDS. Other imaging features that may occasionally be noted include parenchymal masses (see later discussion), dilatation of the Virchow-Robin spaces, hydrocephalous, and cerebral edema.[35,122] Lesions of the Virchow-Robin spaces (called "soap bubble" lesions) are nonenhancing on magnetic resonance imaging and occur at the level of the thalamus, basal ganglia, periventricular white matter, and cerebellum. These lesions correlate with invasion through the perivascular Virchow-Robin spaces seen on autopsy and are characteristic of meningoencephalitis.[8]

India Ink Staining

India ink staining is based on the exclusion of the dye by the *C. neoformans/C. gattii* capsule, which creates a halo around the cell against a background. The sensitivity of India ink staining of CSF has been reported to vary from 50 percent to more than 80 percent. The sensitivity of this assay depends on the number of organisms in the CSF, which may in part be dependent on the immune state of the host.[29] False-positive results may be reported from leukocytes and tissue cells that can be removed by treatment with potassium hydroxide.

Culture and Histopathology

In adults with meningoencephalitis and HIV infection, CSF and blood cultures are positive in 75 to 90 percent and 70 percent of patients, respectively. Similar numbers have been reported in pediatric series.[1] For patients who undergo biopsy (e.g., brain biopsy for cryptococcoma) *C. neoformans/C. gattii* is best visualized with special stains, including silver stain and stains that label the capsule (e.g., mucicarmine and alcian blue). As with other fungi, the cell wall of this organism can be visualized with fluorescence using calcofluor, whereas melanin can be detected with a Fontana-Mason stain. Detection of the organism by immunohistochemistry using capsule-specific antibody and polymerase chain reaction has also been described on a research basis (see Fig. 202-1).[140,146] Although not part of routine clinical practice, quantitative CSF yeast counts have been used on a research basis to predict prognosis and treatment success.[13]

Antigen Detection

The polysaccharide capsule is shed during infection and can be measured in serum, CSF, and bronchoalveolar lavage fluid using two different antibody-based technologies (latex agglutination and enzyme-linked immunosorbent assay). Currently, latex agglutination is the most commonly used assay in clinical laboratories. This is a semi-quantitative assay, which is reported as a titer. The sensitivity and specificity of antigen detection (using CSF or serum) for patients with cryptococcal meningoencephalitis are both more than 95 percent. Antigen may also be detected in the serum in more than 90 percent of patients with disseminated disease.[10] As noted earlier, high CSF antigen titers have been associated with increased mortality, presumably reflecting a high fungal burden. In fact, CSF fungal burden can reach over a million yeasts per milliliter of CSF in advanced cases. In patients with extremely high antigen titers, a false-negative agglutination test may result from a prozone phenomenon. This can be addressed by dilution of samples. Care should therefore be taken in interpreting negative result in patients where there is a high clinical suspicion. Rare false-positive results have been reported in patients with infections secondary to other fungal pathogens such as *Trichosporon* species[98,142] and other microbes.[21] Although antigen detection assays are useful in diagnosis, they have limited utility in following response to therapy. Recently, a lateral flow assay, which shows good agreement with standard antigen testing, has been developed for the diagnosis of cryptococcosis, especially in resource-limited countries.[90] This assay offers the advantages of rapidity, ease of use, and decreased cost.

Complications

Mortality

Untreated cryptococcal meningoencephalitis is uniformly fatal. Despite the development of a variety of antifungal therapies, the mortality associated with cryptococcosis, particularly CNS and disseminated disease, remains high. Worldwide there are more than an estimated one-half million deaths annually, with the majority of these occurring in sub-Saharan Africa and Southeast Asia.[115] Overall, cryptococcal meningitis is the fourth leading infectious cause of death in sub-Saharan Africa, surpassing even tuberculosis.[115] In solid-organ transplant recipients, the mortality associated with cryptococcal meningoencephalitis can approach 40 percent.[64] This is comparable to the 10 to 30 percent mortality for HIV-associated cryptococcal disease in developed countries. In pediatric series, mortality rates have been reported to range between 23 and 38 percent.[1,53,128] Mortality is affected by several variables, including the underlying immune status, the presence of brain involvement, and the availability of appropriate antifungal therapies. Predictors of mortality reflect host factors and yeast burden and include high CSF cryptococcal antigen titer, increased ICP, altered mental status, positive India ink staining, and low CSF white blood cell counts at baseline.[6,36,124]

Increased Intracranial Pressure

Increased ICP is an important and common complication of cryptococcal meningoencephalitis, occurring in as many as 60 percent of affected adult AIDS patients. Increased ICP appears to be more common in *C. gattii* disease. The precise incidence of increased ICP in children with cryptococcal meningoencephalitis is not known but is likely to be similar to that in adults.[89] The entity is well described in children and includes cases of fulminant ICP.[105] The basis of increased ICP in cryptococcal meningoencephalitis remains unknown, but possible mechanisms include (1) inflammation, (2) osmotic effects of shed polysaccharide or mannitol, and (3) obstruction of

normal CSF drainage pathways (e.g., arachnoid villi) by cryptococcal polysaccharide or organisms. In support of this latter hypothesis, increased ICP has been associated in some studies with higher CSF fungal burden and CSF cryptococcal antigen levels but not with inflammation.[52] Furthermore, a difference in the tendencies of strains to elicit increased ICP has been demonstrated in animal models.[43]

Increased ICP is a recognized risk factor for early mortality in cryptococcal meningoencephalitis[52,143] and may correlate with increased CSF fungal burden, increased CSF cryptococcal antigen levels, and failure to sterilize CSF at 14 days. Patients with increased ICP may be symptomatic (e.g., hearing loss, altered mental status, cranial nerve palsy), but increased ICP may not be clinically apparent. Furthermore, computed tomography usually does not reveal ventricular dilatation, although occasional cases of obstructive hydrocephalous on presentation have been described. Appropriate treatment of cryptococcal meningoencephalitis therefore includes the documentation of CSF opening pressures at the initiation of therapy. Symptomatic increased opening pressure (≥250 mm^3 of H_2O) should be managed by serial lumbar punctures with daily withdrawal of CSF. Although there have been no controlled studies to determine the best approach to lowering ICP, the most recent Infectious Diseases Society of America (IDSA) guidelines suggest removal of enough CSF to decrease pressure by 50 percent if it is extremely high or to a normal pressure of less than 200 mm^3 H_2O.[119] Temporary percutaneous lumbar drains or ventriculostomy for persons who require repeated daily lumbar punctures should be considered. Permanent ventriculoperitoneal shunts may be indicated in patients who fail less-invasive methods. Acetazolamide, mannitol, and corticosteroids are generally not indicated in the treatment of increased ICP and may be detrimental. Nonetheless, successful treatment of increased ICP in association with IRIS with corticosteroids has been described in case reports and small series.[85]

Cryptococcoma

Intraparenchymal brain lesions (cryptococcomas) are a recognized complication of cryptococcal meningoencephalitis and have been associated with increased mortality.[22,132] Lesions may be singular or multiple and occur in 11 to 35 percent of patients[122] and can be associated with focal neurologic symptoms and hydrocephalus. Cryptococcomas appear to be more common in non–AIDS patients and with *C. gattii* disease. In a recent study of *C. gattii* meningoencephalitis in Australia, 37 percent of patients developed cryptococcomas.[25] The treatment of cryptococcomas has not been studied in a prospective manner, and current recommendations are based on small series and expert opinion. These recommendations highlight the importance of extended duration for induction and maintenance antifungal therapies. In patients with large lesions (≥3-cm lesion), consideration should be given to surgical debulkment.[119] Repeat imaging is helpful in monitoring the response of brain lesions to therapy, but lesions may persist for a long time and may develop surrounding edema in the context of effective antifungal therapy, which can interfere with the assessment of size. Intraparenchymal brain lesions also occur in the context of IRIS (see next discussion).

IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME

IRIS is thought to occur as a result of improved immune function in the context of residual microbial antigens, which, in turn, produces symptoms secondary to enhanced inflammation. The current paradigm is that IRIS represents a dysregulated immune response with exaggerated Th1 response relative to Th2 inflammation. Support for this hypothesis comes from studies elucidating the CSF cytokine pattern in individuals with IRIS.[141] IRIS in association with cryptococcosis was initially described in AIDS patients treated with HAART, although it has subsequently been described in solid-organ transplant recipients,[138] pregnant patients,[40] and apparently normal hosts.[39] Cryptococcal IRIS may unmask a previously unrecognized infection or occur after treatment of cryptococcosis, resulting in a paradoxical worsening of symptoms. The lack of precise clinical criteria for a diagnosis of cryptococcal IRIS has hindered the study of this phenomenon. Several essential elements of this diagnosis have been proposed, including (1) appearance or worsening of clinical or radiologic manifestations consistent with an inflammatory process, (2) symptoms occurring during receipt of appropriate antifungal therapy that cannot be explained by a newly acquired infection, and (3) negative results of cultures or stable or reduced biomarkers for the initial fungal pathogen during the diagnostic workup for the inflammatory process.[133] Physicians considering a diagnosis of IRIS should exclude progression of infection (owing to inadequate antifungal therapy, antifungal resistance, or worsening immune function) and alternative diagnoses (e.g., other infection, malignancy). Cryptococcal IRIS may present in the form of lymphadenitis, pneumonia, meningitis, or space-occupying lesions in the CNS. Histopathology of affected lymph nodes typically reveals granulomatous inflammation with necrosis and few or absent fungal forms. Cultures typically reveal no growth. Patients with CNS IRIS may develop headache, fever, neck stiffness, and increased ICP, and the associated morbidity and mortality may be significant.[71] In patients with AIDS, cryptococcal IRIS has been reported to occur days to years after initiation of HAART, but typically it occurs weeks to months after HAART is begun. There is usually an associated decline in HIV viral load (at least 1 log_{10}), although changes in $CD4^+$ T cell counts are more variable. Risk factors for cryptococcal IRIS among HIV patients include lower baseline $CD4^+$ T cells, higher HIV viral load, and higher fungal burden at the initiation of therapy. There is considerable controversy on the role of early institution of HAART and the development of IRIS. Some studies highlight early initiation of HAART in the context of cryptococcal meningitis as an important risk factor for IRIS.[93,94,130,139] However, delayed introduction of HAART may be associated with increased mortality from progression of AIDS. Treatment of cryptococcal IRIS has not been studied rigorously, and IRIS

in pediatric cryptococcal disease has not been well documented. Minor IRIS manifestations may resolve spontaneously without specific therapy. Recent IDSA guidelines suggest that prednisone 0.5 to 1 mg/kg in conjunction with antifungal therapy may be helpful for the treatment of CNS cryptococcal IRIS.[119] Symptomatic increased ICP associated with IRIS may also be treated with daily lumbar punctures and CSF removal.

OTHER FORMS OF CRYPTOCOCCOSIS

Besides the CNS and pulmonary tract, *C. neoformans* disease may affect a wide range of organ systems. Primary cutaneous disease may occasionally occur as a result of direct inoculation.[106] More commonly, cutaneous disease represents secondary dissemination, especially in immunocompromised hosts.[118,136] The clinical presentation varies and may include acneiform lesions, purpura, vesicles, nodules, abscesses, ulcers, granulomas, pustules, draining sinuses, and cellulitis. In patients with AIDS, cutaneous cryptococcosis may appear similar to molluscum contagiosum. A high clinical suspicion along with tissue sampling is therefore needed to make a diagnosis. The presence of skin disease should prompt an evaluation for disseminated disease. The prostate has been hypothesized to serve as a sanctuary for *C. neoformans* during antifungal therapy and thereby promote recurrent infection. *C. neoformans* has been isolated from prostatic secretions of AIDS patients with disseminated infection, during and after treatment.[80] The clinical significance of these observations, however, remains unclear; and routine surveillance of prostatic secretions is not indicated.

Congenital Cryptococcosis

Congenital cryptococcosis is rare. Over a dozen cases of cryptococcosis in early infancy (e.g., within the first 3 months of life) have been reported, with a mortality greater than 50 percent.[117] Disease is typically multisystemic, usually with involvement of the central nervous and respiratory systems. Early (e.g., within hours to days of life)[17] and late presentations[72] of cryptococcosis (weeks to months) have been described in neonates. Based on the timing of disease, it has been hypothesized that infection can be transmitted both transplacentally and perinatally, possibly through the aspiration of infected material. The rarity of congenital cryptococcosis among women with active cryptococcosis during pregnancy indicates that the placenta is extremely effective in limiting maternal-fetal transmission. This notion is further supported by several descriptions of cryptococcal placentitis without neonatal disease.[34]

TREATMENT

The treatment of cryptococcosis depends on both the type of disease and the underlying immune status of the host. Although there are clinical differences in cryptococcosis secondary to *C. neoformans* and *C. gattii*, there are no differences in treatment recommendations at the present time. There are no clinical trials addressing the treatment of cryptococcosis in children. Therefore, current pediatric recommendations are based on extrapolations from adult studies using known pharmacokinetic profile of antifungal drugs in children. Routine testing for antifungal susceptibility is not indicated because resistance to amphotericin B and fluconazole is rare. Furthermore, minimal inhibitory concentration (MIC) cutoffs for fluconazole susceptibility have not been established and do not always correlate with clinical outcome. In one study of 487 isolates, only 3 (0.6%) demonstrated a high fluconazole MIC (i.e., ≥16 μg/mL) and all isolates were inhibited by very low concentrations of amphotericin B and exhibited very low MICs to voriconazole and posaconazole.[51] The IDSA guidelines suggest testing for antifungal susceptibilities only in the context of relapsing disease.[119]

Pulmonary Disease

In patients with pulmonary disease, it is essential to determine whether there is associated extrapulmonary involvement. To this end, testing serum for cryptococcal antigen and CSF analysis should be considered in all patients with CNS symptoms and in those with underlying immunosuppression. Isolated pulmonary disease, which is not severe, can be treated with fluconazole. The dosage of fluconazole for pulmonary disease in children is 6 to 12 mg/kg/day for 6 to 12 months based on resolution of symptoms (not to exceed the adult dosage of 400 mg daily). Itraconazole is an alternative therapy for individuals who cannot tolerate fluconazole, and the successful use of extended-spectrum azoles (e.g., voriconazole, posaconazole) has been described. Patients with evidence of extrapulmonary disease or severe pulmonary involvement should be treated with the same approach used to treat meningoencephalitis. Azoles are contraindicated in early pregnancy.

Central Nervous System Disease

The currently recommended treatment strategy for cryptococcal meningoencephalitis involves a staged approach using amphotericin B with flucytosine in combination for induction followed by consolidation treatment with fluconazole. The IDSA Guidelines for the Management of Cryptococcal Disease recommend amphotericin B at 0.7 to 1 mg/kg/day plus flucytosine 100 mg/kg/day for the treatment of cryptococcal meningitis.[119] In children, who tolerate amphotericin B better than adults, the higher dosage (e.g., 1 mg/kg /day) is preferred. The combination of amphotericin B and flucytosine has been demonstrated to be synergistic in vitro and result in improved outcomes in both animal models and clinical studies. Both amphotericin B and flucytosine have significant toxicities, and patients must be closely monitored for these. The duration of induction therapy is typically 2 weeks but should be individualized. A longer duration of induction should be considered under the following conditions: lack of clinical improvement, positive CSF cultures at 2 weeks, the inability to administer flucytosine, and non-HIV and nontransplant recipients. Most

meningoencephalitis studies have been done in patients with AIDS and transplant recipients, and the duration of induction therapy for other individuals has not been well studied. Repeated CSF examination at 14 days should be considered to document CSF sterilization. Patients with persistently positive cultures should continue induction therapy, and CSF analysis should be repeated every 2 weeks until CSF is sterile. If flucytosine cannot be administered, amphotericin B administered alone is an acceptable alternative. In patients whose renal function is impaired, lipid formulations of amphotericin B (liposomal amphotericin B, 3 to 6 mg/kg/day, or amphotericin B lipid complex, 5 mg/kg) may be substituted. Lipid formulations of amphotericin are also recommended as first-line agents for solid-organ transplant recipients with cryptococcosis. In resource-limited regions where amphotericin B is not readily available, high-dose fluconazole (1200 mg/day) with flucytosine has been studied as an alternative in adults.[108] After successful induction therapy, children should be treated with fluconazole 12 mg/kg/day (adult dosage, 400 mg) for 8 weeks.

Secondary Prophylaxis

After successful therapy for pneumonia and meningoencephalitis, children with AIDS should be maintained on suppressive fluconazole therapy (6 to 10 mg/kg/day) to prevent recurrence of disease. In adults, the current recommendations are to continue fluconazole until patients demonstrate a response to HAART, as manifested by a CD4 cell count greater than 100/μL and a sustained undetectable or very low HIV RNA level for 3 months (with a minimum of 12 months of antifungal therapy).[119] Although this approach is generally applied to children, there are little clinical data to support this practice and it should be undertaken with caution and with close observation for recurrence. A 6- to 12-month period of suppressive fluconazole therapy should also be considered in organ transplant recipients.[119]

Adjuvant Interferon Gamma

Consistent with its action as a Th1 cytokine, interferon (IFN)-γ plays a central role in the effective host response to cryptococcosis in animal models.[9,24] Furthermore, exogenously administered IFN-γ enhances resistance and potentiates the effects of amphotericin B in these models.[28,58] A phase II study demonstrated that adjuvant IFN-γ is well tolerated in patients with cryptococcal meningoencephalitis.[113] In one study it was suggested that the addition of IFN-γ to initial induction with amphotericin B/flucytosine results in quicker CSF sterilization, a marker that has previously been associated with clinical success.[67] This study, however, was not powered to detect differences in mortality. Current IDSA guidelines recommend that adjuvant IFN-γ should be considered in refractory cases.[119]

Primary Prophylaxis

In resource-limited regions where HAART is not widely available there has been increased interest in fluconazole prophylaxis to prevent cryptococcosis. The rationale for this approach lies in the high incidence and mortality of cryptococcosis in these regions. Two different strategies have been applied with promising results. With the first approach, at-risk HIV-infected individuals are regularly screened for serum cryptococcal antigenemia and treated with fluconazole if they are antigenemic but without overt cryptococcosis.[100] Cryptococcal antigenemia is a marker for the subsequent development of symptomatic cryptococcosis and for death from cryptococcosis and other causes.[88] In essence, this approach represents treatment of incipient disease and is similar to preemptive strategy used in CMV disease in solid-organ transplant recipients. This approach may become more attractive with the recent development of the lateral flow assay for antigen detection. With the second approach, all at-risk individuals (i.e., those with CD4 T cells <200/μL) are prophylactically treated with fluconazole. In a Ugandan prospective, double-blind randomized controlled trial, fluconazole prophylaxis for all patients with CD4 T cells less than 200/μL was effective in preventing cryptococcosis and cryptococcosis-associated death.[116]

CHAPTER 203

Histoplasmosis

Martin B. Kleiman

Histoplasmosis is the most common pulmonary and systemic mycosis in humans and affects millions of people.[17,69,238,506] Although most infections occur in areas where the etiologic agent, *Histoplasma capsulatum*, is highly endemic, histoplasmosis is being recognized in areas not previously known to be endemic. A substantial proportion of infections with *H. capsulatum* occur in the United States, where approximately 500,000 individuals are infected annually.[487] Of these, an estimated 55,000 to 200,000 infected individuals become symptomatic and 1,500 to 4,000 require hospitalization.[77] The significance of *H. capsulatum* as a cause of opportunistic infection has escalated in proportion to the increasing numbers of individuals who are immunosuppressed.[304]

H. capsulatum was described first in 1906 by Darling[239] while he was examining autopsy specimens of a man from Martinique who died of a chronic, wasting illness. He observed organisms within histiocytes and thought them to be encapsulated plasmodia; the illness caused by this previously unrecognized pathogen was named reticuloendothelial cytomycosis.[239] In 1932, Dodd and Tompkins described intracellular *H. capsulatum* in the peripheral blood smear of a febrile child and DeMonbreum isolated the organism from this child and correctly classified it as a fungus. In 1944, Christie and Peterson[76] developed histoplasmin and, after cutaneous inoculation, showed a localized reaction in a child with histoplasmosis.

In 1945, Parsons and Zarafonetis characterized the disease as rare and usually fatal after studying 71 patients with disseminated histoplasmosis. Using histoplasmin skin testing, however, Christie and Peterson[76] showed histoplasmosis to be a common and usually a mild disease. They also determined that histoplasmosis was the cause of pulmonary calcifications in patients who were presumed to have had tuberculosis, but in whom tuberculin skin tests were negative. Demonstration of the organism in soil and air samples in the late 1940s and early 1950s confirmed the natural habitat and transmission of the pathogen.[13,382,488]

THE ORGANISM

Histoplasma capsulatum var. *capsulatum*, the anamorphic (asexual) form of the organism, is a thermally dimorphic, saprophytic fungus of the class Ascomycetes, family Gymnoascaceae, subdivision Ascomycotina. The mold form displays heterothallic sexual reproduction with plus (+) and minus (–) mating types. Ninety percent of infections are caused by the minus type. The ascomycetous teleomorph produced by mating opposite types is termed *Emmonsiella capsulata*; the current taxonomy of this perfect (sexual) form is *Ajellomyces capsulatus*. Because the fungus is isolated in the laboratory as the anamorph, the more common name *H. capsulatum* is used in this text.

At temperatures of 25° C to 30° C, the mold grows as a fluffy colony with an aerial mycelium that varies from white to buff brown. Mycelia, small oval microconidia (2 to 4 μm) that are attached laterally to hyphae, and tuberculate and nontuberculate macroconidia (8 to 16 μm) are seen microscopically (Fig. 203-1). Growth is slow, with 1 to 2 weeks required for laboratory strains and 8 to 12 weeks for growth from clinical specimens. When cultured at 37° C on enriched media containing cysteine, the mold transforms to the yeast form in 7 to 10 days. The small, heaped, yellow-white, pasty colonies appear microscopically as ovoid, budding yeasts (1 to 3 μm × 3 to 5 μm) with rare pseudohyphae.[332]

In its natural habitat, the soil, *H. capsulatum* exists as spore-bearing mycelia. It survives best in moist (95% to 100% humidity), nitrogen-rich soil at temperatures of 37° C or greater and can be found 1 mile below the soil surface.[467,487] The droppings of chickens, blackbirds, and starlings contain nutrients that promote growth, and, at least in the case of chickens, may contain substances that discourage the growth of competitive organisms. Many species of colonial New World bats become infected and excrete the fungus in their guano, which contains substances that encourage fungal growth.[134,277,442,443] The migratory behavior of bats has been shown to be associated with genetic variation and both the geographic distribution and the ecotype dispersion of *H. capsulatum*.[444] Birds excrete the fungus in droppings yet remain uninfected, probably because of their high body temperature. *H. capsulatum* can remain viable in droppings or other contaminated sites for many years.[516]

Early techniques used to differentiate strains of *H. capsulatum* included serotyping and chemotyping.[118] Examinations of restriction fragment length polymorphisms of DNA have delineated three broad classes that exhibit geographic and possibly clinical differences.[126,242,470] Class 2 strains are found most frequently in North America, and class 3 strains are found in Central and South America. Class 1 strains are isolated almost exclusively from immunocompromised patients. Individual strains within each class have been examined further with additional nucleic acid–based and genome-wide approaches to reveal considerable genetic diversity.[68,220,312,444] Such strain differences are useful for molecular epidemiologic investigations.[220,311,441,445,537] Studies have suggested that

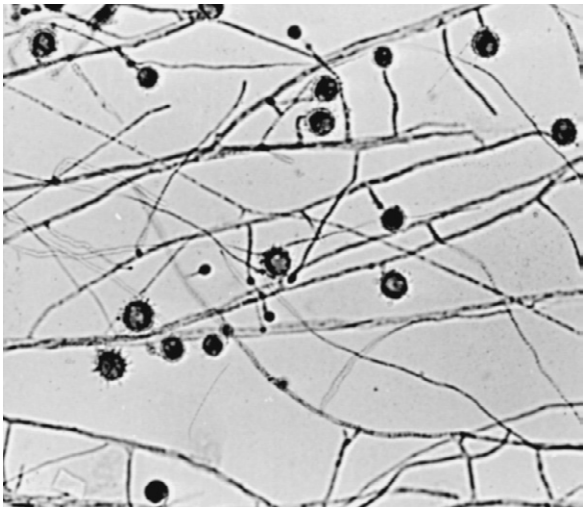

FIGURE 203-1 ■ Culture of *Histoplasma capsulatum* from sputum illustrating tuberculate macroaleuriospores and microaleuriospores (lactophenol cotton blue, ×52).

patients with acquired immunodeficiency syndrome (AIDS) may be infected with less virulent, temperature-sensitive variants of *H. capsulatum*.[427] Additional investigations using molecular methodology have suggested that genetic differences in the pathogen may underlie clinical differences.[197,235,313]

Histoplasma duboisii, the cause of African histoplasmosis, was reclassified as a variant of *H. capsulatum* when it was shown that mating of isolates from each type produced cleistothecia and ascospores identical to those of *E. capsulata* (now termed *A. capsulatus*).[382] *H. capsulatum* var. *duboisii* is indistinguishable from *H. capsulatum* var. *capsulatum* in its mycelial stage; in its tissue phase it appears as thick-walled oval yeast forms that are 10 to 15 μm in diameter. Infections caused by *H. capsulatum* var. *duboisii* have been described across central and western Africa, and cases occur along with histoplasmosis caused by *H. capsulatum*.[179,281,332] A more recent phylogeographic analysis[235] of both varieties that cause human disease and another, *H. capsulatum* var. *farciminosum* (an Old World horse pathogen), using DNA sequencing of four independent protein-coding genes questioned the validity of the classification.[65]

EPIDEMIOLOGY

Histoplasmosis is almost always acquired when sites contaminated with *H. capsulatum* are disturbed and spores are aerosolized and inhaled. The early understanding of its global epidemiology and clinical signs was skewed by analyses of localized outbreaks after exposure to large inocula. A more accurate picture emerged when skin test epidemiology, environmental cultures, vectors, and analyses of patient exposures were considered.[65]

Histoplasmosis has been reported worldwide[303] in tropical, subtropical, and, most frequently, temperate areas. Regions with high rates of infection are considered endemic. The majority of illnesses are sporadic and unassociated with exposure to a specific site or specific activity. They are presumed to result when environmental conditions are conducive to fungal growth and when dry, windy conditions or other events or activities facilitate the aerosolization of spores. Although early reports emphasized that the infection usually was associated with occupational exposure in primarily rural environments, infection is recognized commonly in urban areas,[221,283] where it may affect many people.[510] Asymptomatic infections are common in children and are usually unrecognized.[50,185,212] In a highly endemic area, skin test reactivity was 34 percent in children younger than 2 years, 55 percent between 2 and 4 years, and 77 percent in 10-year-olds.[538] Rates accelerated in summer.

The incidence of infection varies widely in endemic regions. Within short distances of areas in which residents show a moderate rate of skin test reactivity may be those in which the incidence is considerably higher. Still more localized and very heavily contaminated sites, termed *microfoci*, may be found in which localized, sometimes severe, outbreaks occur. Because the droppings of birds and bats[26,285] accelerate growth of the mycelial form in the environment, implicated sites have included blackbird and pigeon roosting areas, chicken houses, bat-infested caves,[214] attics, chimneys, old structures, and decaying woodpiles and trees. Activities that disturb these areas have been implicated in localized outbreaks.[212,363,487] Infections in children have been associated with exploring caves, playing in barns or hollow trees, cleaning abandoned buildings, cutting firewood or decayed tree stumps, renovation of older homes, digging in contaminated sites, excavation/demolition of buildings, cleaning seldom-used fireplaces, and exposure to fungal aerosols that gain access to air intakes.[70,283]

The geographic distribution of *H. capsulatum* skin test reactivity among 275,558 U.S. Navy recruits was determined[131,130] between 1958 and 1965. The highest incidence was found in residents of the Ohio-Mississippi-Missouri, the St. Lawrence, and the Rio Grande River Valleys. In four states (Arkansas, Kentucky, Missouri, and Tennessee), the percentage of positive adult reactors ranged from 57 to 68 percent. In the adjacent states (Illinois, Indiana, Ohio, and Oklahoma), reactivity ranged from 50 to 73 percent among adults in farm areas. Of the other seven states in the endemic area, lifetime prevalence rates exceeding 50 percent were shown in one or more counties. Epidemiologic studies have not been repeated, and population shifts and changes in land use may alter these patterns.[258] In Latin America,[66] areas of high prevalence include Venezuela,[293] Colombia,[23,314] Ecuador,[339] Brazil,[33] Paraguay, Uruguay, and Argentina.[86,293] Disseminated histoplasmosis is often recognized as AIDS defining.[315]

Analyses of point-source and sustained outbreaks offer some means of assessing the epidemiology and clinical spectrum of infections. An outbreak in Indianapolis, Indiana, affected an estimated 100,000 individuals within a 400-square-mile area and lasted nearly 1 year.[510] Illnesses were identified in 435 individuals (including 49 children younger than 15 years old), and disseminated disease developed in 46. Those aged 15 to 34 years were more likely to become infected than were other age groups. An equal sex distribution of infections

occurred before puberty; males predominated in a 3:1 ratio in older individuals. Localized outbreaks related to high-risk sites and activities[60,395,464] are well documented. Isolated cases may not be associated readily with such activities. Infections acquired during travel* and/or migration[17,54,215,334] to endemic regions[20,137,154,327,477] are being reported more frequently. Infections acquired in areas not recognized as endemic, such as occurred in college students whose only known common exposure was vacationing at a hotel in Mexico,[309] require consideration of the diagnosis in patients with compatible clinical findings.[18,57,63,394] Rarely, infections occur in nonendemic areas and may result from reactivation of quiescent infection in patients who become immunosuppressed.[17,53,218,457]

Although various wild[243] and domestic[51] animals may become infected, transmission of histoplasmosis to humans does not occur. Infection of an infant after exposure to a pillow that contained contaminated feathers has been reported.[64] Vertical transmission, in an area not endemic for histoplasmosis, of both disseminated histoplasmosis and HIV infection has been reported in the 5-week-old infant of a mother with both HIV infection and disseminated histoplasmosis.[14] Although a case of sexual transmission that resulted from exposure to mucosal lesions of a patient with disseminated histoplasmosis has been described,[415] human-to-human transmission is exceedingly rare. Transmission has been confirmed, with the use of molecular typing methodology, in the recipients of two cadaveric organs from a donor who had resided in an endemic area.[270] Infections caused by inoculation of contaminated material from either the environment or laboratory accidents are also rare.[55]

PATHOPHYSIOLOGY

H. capsulatum has unique interactions with human macrophages, dendritic cells, and neutrophils,[322,326,408] the outcomes of which contribute to its success as a pathogen. Key are its ability to infect and gain access to macrophages[526]; alter the intracellular environment thereby allowing it to survive, replicate, and disseminate[103,129,171]; remain viable during clinically unapparent infection; and become reactivated when host immune factors permit.[61] Inhalation of fungal spores induces a brisk innate immune response that is followed by an acquired immune response after about 2 weeks. During these events, the fungus induces an orderly modulation of the host inflammatory and cytokine and chemokine responses.[251] Production of cytokines begins within 24 hours of primary infection and continues for approximately 3 weeks, bridging both the innate and acquired immune responses. Successful clearance of the infection depends primarily on the functional integrity of cellular immunity.† The clinical manifestations and outcome are determined by this complex interplay of events. Variation of responses to infection in inbred murine models has shown that genetic factors both influence shifts of immune cell populations and alter disease outcomes.[294]

The length of the incubation period of histoplasmosis varies inversely with the size of the inoculum, the integrity of the host immune response, the presence of immunity from previous infection, and strain-related differences in fungal virulence.[128,168,248] Although the range of incubation periods is reported to be 1 to 3 weeks in nonimmune hosts, it has been based largely on data from point-source outbreaks in which the time of the event leading to exposure is readily determined. In these settings, the size of the infecting inocula is probably larger, however, than those resulting in sporadic infections.[65,98] Because most infections occur sporadically and either are asymptomatic or result in nonspecific and self-limited flulike illnesses that are not diagnosed, the upper range may be longer. In patients who retain specific cellular (protective) immunity from previous infection, reexposure results in milder symptoms and shorter incubation periods, usually 4 to 7 days.[65] A very small proportion of otherwise normal infants as well as individuals of any age with primary or acquired cellular immune dysfunction are more likely to experience symptomatic illness after exposure.[168]

In experimental animals, pneumonitis develops after inhalation of *H. capsulatum* microconidia or mycelial fragments.[34] Because of their smaller size, microconidia enter terminal alveoli and, within 2 to 3 days, germinate and convert to yeast forms. Dimorphism appears to be a major determinant of virulence[206]; chemical blockage of the transition has been shown to impair virulence[329] in a murine model.[306] Progress in understanding the molecular cell biology and genetics of the mold-to-yeast transition has been reviewed.[213] Molecular techniques have identified two genes *(URA5*, *CBPI)* that have a role in pathogenesis.[525,527]

Additional determinants of fungal virulence have been described and include roles for α-1,3-glucan.[378] In the first week, a neutrophil response occurs at the site of the infection[35]; it is followed in approximately 2 weeks by the accumulation of helper T lymphocytes and macrophages.[365] The yeast forms attach to integrins of the CD11/CD18 group of cell surface receptors and enter neutrophils[403,408] and macrophages.[56,439] This process may be an adaptive microbe entry mechanism that enables the organism to evade the host oxidative burst response associated with host-directed opsonophagocytosis.[527] Human neutrophils possess fungistatic activity that resides within azurophilic granules.[52,323] Neutrophils have been shown to play a role in the primary immune response in a murine model[542]; however, depletion of neutrophils in a systemic model of secondary infection did not alter the course. In an animal model, phagocyte-produced reactive oxygen species participate in the immune response while superoxide dismutase facilitates pathogenesis by detoxifying host-derived reactive oxygen, thereby enabling survival of *Histoplasma*.[536]

Traditional opsonophagocytosis facilitated by binding to complement or to immunoglobulin after the development of humoral immunity also occurs.[527] This process exposes the yeast to the full array of antimicrobial defense mechanisms.[526] Microbe-directed binding using a specific ligand (adhesin) on the yeast's surface has been identified

*References 21, 54, 64, 138, 229-231, 344.
†References 24, 168, 232, 333, 374, 540.

as *H. capsulatum* HSP60.[16,58,278] This heat shock protein also induces immunity to lethal and sublethal infection in a mouse model, a complex effect related to its ability to stimulate $CD4^+$ T lymphocytes.[106] HSP60 has also been shown to both orchestrate the adaptation of the fungus to temperature stress[181] and impact macrophage effector function.[180]

The yeast forms seem to have a competitive advantage within the membrane-bound vacuoles of macrophages,[320,321] and the asylum seems to protect it from pulmonary collectin-mediated killing.[295] Both fungal growth and virulence are exquisitely sensitive to the availability of iron.[204] Zinc deprivation is also thought to be a host defense mechanism utilized by macrophages in a mouse model.[522] Additional strategies used by the organism to survive and replicate in mouse models include increasing the alkalinity, tolerating nutrient starvation, and resisting the toxic effects of host reactive oxygen and nitrogen intermediates, degradative enzymes, and antimicrobial peptides.[205,527] Murine macrophages differ from human macrophages because the latter mount a respiratory burst without the need for opsonization, as is required for murine macrophages. Lysis of infected cells releases additional yeasts and results in infection of increased numbers of macrophages. During this period of fungal sequestration and replication, lymphohematogenous dissemination distributes yeast from the lungs to the reticuloendothelial system and to other organs.[320] Without the development of an effective cellular immune response, the infection is lethal.[321,365]

Although infection usually results in a brisk antibody response, humoral immunity does not contribute substantially to primary or secondary immunity.[288,329,396] A mouse model has shown, however, that antibodies to a surface protein of the fungus altered the intracellular fate of the fungus and mediated protection.[19] Human dendritic cells that reside in the lung serve to link the innate and adaptive immune responses. Because they are more efficient antigen-presenting cells than alveolar macrophages, dendritic cells use the fibronectin receptor, phagocytose and rapidly degrade the organism, present *H. capsulatum* antigen for lymphocyte proliferation, and facilitate the induction of cell-mediated immunity.[161,321,438] Dendritic cells also have been shown to cross present exogenous antigen through uptake of apoptotic macrophage-associated fungal antigens (cross presentation).[272] Some of the strategies used by the yeast that facilitate its survival and replication within macrophages, such as prevention of phagolysosomal fusion, do not occur in dendritic cells. Destruction of yeast within human dendritic cells is an important role within the innate immune response[321] and seems to result from exposure to lysosomal hydrolases.[160] Conidia transformation into yeastlike forms does not take place within dendritic cells.[326]

After they participate in the innate immune response, several endogenous cytokines[251] induced by the development of cellular immunity[321] activate macrophages, which then function as primary cellular effectors that control the infection.[103,320,408] Cytokines that play key roles in the resolution of primary or secondary infection (protective immunity) in animal models include tumor necrosis factor-α (TNF-α),* interferon-γ (IFN-γ),[10,11,83,255,469] interleukin (IL)-4,[101] IL-12,[11,62,543,544] IL-1,[110] and granulocyte-macrophage colony-stimulating factor.[9,12,104,109,422] The effect of IL-12 results from its induction of IFN-γ; it is active in primary infection but not in reinfection.[11] Deficiency of IL-10 has been shown to confer a salutary effect on histoplasmosis in a murine model.[107] Apoptosis, a crucial element of protective immunity in the mouse model, when inhibited, is accompanied by increased production of IL-4 and IL-10 as well as by exacerbation of the severity of infection.[8]

Cytokines that activate human macrophages and induce them to become fungistatic are granulocyte-macrophage colony-stimulating factor, macrophage-stimulating factor, and IL-3[101]; the mechanisms by which the colony-stimulating factors promote fungistatic activity are not fully elucidated but have been shown to not require phagosome acidification to kill and degrade yeast.[324] TNF-α[101,108,259,524] is a central and critical mediator of resistance in mice and humans, although its effects on cellular targets differ.[190] Human macrophages also express antifungal activity that is not cytokine dependent. The latter mechanism is stimulated by attachment of macrophages to type 1 collagen matrices and is mediated at least partly by overcoming the ability of yeasts to inhibit phagolysosomal fusion.[325] Leukotrienes are required for control of chronic infections, amplifying innate and adaptive immune responses in a mouse model.[407]

In addition to macrophages, specific T-cell subpopulations also are capable of killing *H. capsulatum*. $CD4^+$ cells have been shown to be essential for fungal clearance in mouse models.[102,164,271] This comports with observations showing that the risk for severe histoplasmosis developing in adults with human immunodeficiency virus (HIV) infection increases when the $CD4^+$ count is less than 200/μL.[501] Idiopathic deficiency of $CD4^+$ cells has also been associated with opportunistic infection caused by *H. capsulatum*.[125] $CD8^+$ cells also mediate immunity in mice,[271,272] but their contribution is not as significant as that of $CD4^+$ cells. $CD8^+$ cell clearance of *H. capsulatum* involves both perforin-dependent and perforin-independent mechanisms.[541] IFN-γ and TNF-α also work in concert with cytolytic mechanisms to provide protective immunity against *H. capsulatum*.[541] The role of natural killer cells has been studied in murine models.[349] Natural killer cells participate to a limited degree in the immune response in immunocompetent animals and play a more substantial role in animals depleted of T cells.[321]

In immunocompetent hosts, cellular immunity is suppressed[353] early in the course of histoplasmosis, especially in disseminated histoplasmosis of infancy.[79,333] Cellular immune function returns to normal after 4 to 6 weeks of treatment. In the mouse model, *H. capsulatum* infection is associated with the generation of suppressor T-cell activity; this activity depresses the production of T-cell–dependent, delayed-type hypersensitivity, mitogen-induced lymphocyte transformation, and cytotoxic activity.[25] T-cell immunity develops 10 to 21 days after

*References 10, 12, 13, 101, 104, 531, 542.

exposure, and splenic suppressor T-cell numbers decrease while helper T-cell numbers increase.

In a study of the cellular immune responses of patients infected with HIV-1 and with recent onset of histoplasmosis, all of the patients had nonreactive skin tests. Lymphoproliferative responses and IFN-γ production were depressed in patients with $CD4^+$ counts of 200 to 500 cells/μL; lymphoproliferative responses approached normal in patients with $CD4^+$ counts above 500 cells/μL.[463] In addition to having defective cellular immunity resulting from decreased numbers of $CD4^+$ cells, the macrophages of patients with HIV infection have impaired ability to control *H. capsulatum*. This results from a profound defect in their ability to recognize and bind to yeast and from permissiveness for intracellular fungal growth.[72] The HIV envelope glycoprotein gp120 seems to play a role in inhibiting phagocytosis of *H. capsulatum* by macrophages, but it is not responsible for the capacity for accelerated growth of yeast within macrophages.[73]

PATHOLOGY

With the exception of patients who have severe progressive disseminated infection, particularly those with preexisting primary or acquired cellular immune dysfunction, histopathologic findings in histoplasmosis are characterized by granulomatous inflammation, usually in association with caseating and noncaseating granulomas. The mature granuloma serves to both localize inflammation and inhibit fungal growth. The effectiveness of this pathologic response is reflected in the substantial prevalence of asymptomatic and self-limited infections in geographic regions in which skin test reactivity exceeds 90 percent. Another potential and clinically important outcome of this microenvironment is late reactivation of the infection in the event of acquired immune dysfunction.[200,466]

Granulomas appear after the development of an effective acquired immune response; the cellular elements consist primarily of mononuclear phagocytes and lymphocytes, largely T cells. Langerhans giant cells often are present; and typical yeast forms occasionally, but not consistently, are visible within macrophages. Inflammation ultimately progresses to fibrosis and often is accompanied by calcification.[168] The rate of calcification is age dependent, and it may occur within months in children and over several years in adults.[168,432] Exuberant granulomatous inflammation or fibrosis or both can result in obstruction or dysfunction of adjacent mediastinal or, less commonly, abdominal[379] structures. Although viable yeasts may remain in quiescent granulomas, they are few and rarely seen. In areas endemic for histoplasmosis, old granulomas in the lung, bone marrow, or other sites may be seen as incidental findings, the significance of which depends on clinical assessment. Yeasts almost never are observed in histologic sections of extensive fibrosis in late histoplasmosis.

In patients with acute progressive manifestations of histoplasmosis, especially those with preexisting cellular immune dysfunction,[140,307] or in otherwise normal infants, the inflammatory response is impaired and granuloma formation is poor.[307] In these instances, extensive parasitization of macrophages by yeasts occurs, and organisms may be seen readily in various reticuloendothelial structures, especially the bone marrow, and sometimes within leukocytes in the peripheral blood.[333] Many other organ systems are often involved. The histopathologic findings in central nervous system (CNS) infection consist of granulomatous basilar meningeal and vascular inflammation, perineural inflammatory changes in cranial nerves, and the presence of many organisms at the periphery of mass lesions.[493] In disseminated infections, the adrenals frequently are affected.[29,178,437] A spectrum of pathologic abnormalities of the gastrointestinal tract may also occur.[28,85,254,345]

CLINICAL MANIFESTATIONS

Approximately 95 percent of infections caused by *H. capsulatum* occur in normal individuals and either are asymptomatic or cause brief, self-limited illnesses with no sequelae. The only residual findings are the incidental radiographic demonstration of typical granulomas in the lung parenchyma and/or calcifications in the hilar mediastinal lymph nodes or spleen. In immunocompetent hosts, the size of the inoculum probably is the principal determinant of whether infection is accompanied by clinical symptoms. After exposure to small inocula, only 1 percent of individuals develop symptoms, whereas after heavy exposure,[487] 50 to 100 percent become ill. Additionally, the symptoms that develop are more severe in individuals who are exposed to large inocula. Severity may be reduced in individuals with preexisting immunity derived from previous infection. Protection is incomplete, however, and severe disease can occur after reexposure to a large inoculum.

A crucial determinant of susceptibility and disease severity also is host dependent. Individuals with primary or acquired disorders of cellular immunity and otherwise normal infants younger than 1 year old have a disproportionately high risk for developing symptoms after exposure. These groups are at far greater risk for progression of early dissemination. The precise factor or factors that predispose to a higher risk for progressive dissemination in infections acquired during infancy have not been determined.[372]

As with other endemic mycoses, histoplasmosis begins as an acute inflammatory pneumonitis, undergoes self-limited or progressive dissemination, and requires an effective host immune response for its control. Clinical manifestations (Table 203-1) vary because they result from any or all of the following: the nonspecific systemic effects caused by the infection, symptoms resulting from either the primary inflammatory focus or perturbation of function of anatomic structures adjacent to primary sites of inflammation, hypersensitivity phenomena resulting from the acquired immune response, symptoms caused by hematogenously infected sites, life-threatening multisystem symptoms resulting from progressive parasitization of the reticuloendothelial and other organ systems, symptoms caused by chronically progressive forms of

pneumonitis or dissemination, or exacerbation of quiescent disease. Recognition, confirmation of the diagnosis, and selection of prudent therapeutic options require understanding of these diverse clinical manifestations. Aside from patients with preexisting conditions or those receiving therapy that impairs immune function, all patients with serious disseminated disease, persistent antigenuria after completion of therapy, relapse, or recurrent infections should undergo comprehensive assessment of immune function.

Pulmonary Histoplasmosis

The most common symptoms of acute primary histoplasmosis encompass a spectrum[300,496] of respiratory and systemic complaints of varying severity. Eighty percent of infections that are accompanied by symptoms are mild, undifferentiated, flulike illnesses with cough, myalgia, headache, and variable low-grade fever. Symptoms usually are self-limited and resolve in 3 to 5 days.[487] In cases of more significant fungal exposure, fever is present, and symptoms can include headache, myalgia, chills, persistent cough, and nonpleuritic chest pain.[168] Illness may persist for 2 weeks and be associated with nausea, asthenia, weight loss, and/or fatigue. This manifestation also is self-limited, although fatigue and weight loss improve slowly after the fever resolves.

In primary infections that last longer than 2 weeks, fever persists and is often accompanied by greater weight loss, chills, night sweats, fatigue, and/or chest pain. The chest pain that occurs in histoplasmosis typically is nonpleuritic; may be substernal, posterior, or lateralized; usually is brief in duration; and recurs frequently. This pattern of chest pain may last from a week to several months.[168] Wheezing may be an early symptom.[59,476] Hepatosplenomegaly occasionally is present, although its occurrence should raise suspicion of the early onset of progressive dissemination. In these prolonged illnesses, resolution without treatment may occur, but with the safe and effective oral antifungal agents available, most experts recommend treatment with antifungal therapy.

Finally, in acute primary infections that occur after exposure to a large inoculum of spores, the resulting diffuse pneumonitis may be associated with severe symptoms, particularly dyspnea or adult respiratory distress syndrome early in the infection. In these instances, the ordinarily self-limited early dissemination has a high risk for becoming progressive, and treatment is required. After development of the respiratory complaints that accompany primary infection, rheumatologic syndromes may be seen within several months of infection. They usually consist of erythema multiforme,[305] erythema nodosum,[168,276,343,409] acute migratory polyarthritis, or any combination of these conditions.[81,388] Although histoplasmosis-induced erythema nodosum is seen during childhood and adolescence, arthritis is uncommon. The rheumatologic symptoms are immune mediated and usually self-limited or respond to mild anti-inflammatory therapy.

Various symptoms may result from complications arising from intrathoracic or, less commonly, intra-abdominal lymphadenitis caused by *H. capsulatum*. One of the most problematic, often termed *mediastinal lymphadenitis*, is acute primary infection accompanied by fever, weight loss, and a mediastinal mass visible on chest radiograph. The presence of mediastinal lymphadenopathy in the absence of any recognized clinical symptoms often require definitive diagnosis to exclude a neoplasm, especially lymphoma.[149,529] Pediatric series that have examined the definitive diagnosis of such manifestations have found rates of histoplasmosis to range from 1 to 57 percent,[44,149,475,529] a discrepancy best explained by considering whether the study population lived in an endemic region. In a highly endemic region, the cause of a mass within the middle mediastinum was histoplasmosis if the *Histoplasma* complement-fixation (CF) titer was greater than 1:16.[149]

Complications of acute primary histoplasmosis may be seen when granulomatous lymphadenitis results in inflammation, compression, or obstruction of contiguous structures within the thorax; this manifestation occasionally is termed *mediastinal granuloma*. Structures most commonly affected are, in decreasing order of frequency, the bronchi, trachea, pericardium, pulmonary vasculature and great vessels, lymphatics,[459] esophagus, nerves,[124,348,381,528] and endovascular infections of prosthetic endografts or valves.[196,222] Symptoms include bronchial compression or obstruction, or both,[429] which sometimes are associated with distal pneumonitis; pericarditis; pulmonary infarction; esophageal diverticula, fistula formation, or dysmotility, alone or in combination; tracheoesophageal fistula formation; phrenic or recurrent laryngeal nerve palsy; or, in endovascular infections,

embolic phenomena. Presumably because of their more pliable airways, children are more susceptible than adults to tracheobronchial compression as a result of encroachment by enlarged lymph nodes.[153] The risk for involvement of contiguous structures by such mediastinal granulomas may be related to the thickness of the capsule, rather than to the overall size of the node.[168]

In highly endemic regions, histoplasmosis is the cause of 25 percent of acute pericarditis cases; approximately one fourth of patients have symptoms of tamponade,[488] although it rarely is seen in children. In almost all instances, pericardial effusion results from inflammation caused by infected lymph nodes adjacent to the pericardium and not by frank fungal pericarditis.[535] The pericardial fluid is exudative, bloody, and almost always sterile.[510] Most patients with *Histoplasma* pericarditis quickly improve with administration of nonsteroidal anti-inflammatory drugs, and neither acute drainage nor pericardiectomy is needed. Rarely, contiguous adenitis or broncholiths erode through the pericardium and cause fungal contamination of the pericardial space.[168,535] Pleural effusions occur very rarely in children with histoplasmosis, and, similar to pericarditis, seem to result from pleural inflammatory reactions to adjacent granulomas; cultures of pleural fluid are negative.[371] Chylothorax caused by extrinsic compression of the thoracic duct by histoplasmosis-induced lymphadenitis has been reported to occur in a 3-year-old.[459] Broncholithiasis may result from calcifications that erode through bronchi[39] but rarely occurs in children. Lower cervical[296,488] or supraclavicular adenitis is an infrequent manifestation of histoplasmosis and usually is seen in association with mediastinal involvement. Lymphadenitis occasionally affects intra-abdominal lymph nodes and has been reported to cause biliary tract obstruction[5,350,379] in children.

Subacute or chronic manifestations of intrathoracic histoplasmosis may occur in children, although they most commonly affect older adults. Of these entities, diffuse mediastinal fibrosis may affect adolescents, albeit infrequently. In these rare instances, granulomatous inflammation progresses to dense fibrosis and may cause stenosis, obstruction, or malfunction of contiguous critical mediastinal structures. Although symptoms are similar to those caused by active granulomatous inflammation that impairs the function of these structures, the fibrosis is progressive and irreversible and responds to neither antifungal therapy nor anti-inflammatory agents.[282] Common complications include the superior vena cava syndrome and/or stenosis or obstruction of the trachea, bronchi, pulmonary artery, or esophagus.[190] Late constrictive pericarditis has been reported[168,530] to develop in 14 percent of adults with *Histoplasma* pericarditis, but data have been descriptive. Histoplasmosis has been documented to occur in a 14-year-old who presented with late constrictive peridarditis.[530] Long-term data in children are lacking; in my personal experience of 35 years of research in a highly endemic area I have failed to identify histoplasmosis-induced constrictive pericarditis during childhood.

Additional late complications of intrathoracic histoplasmosis are seen primarily in adults and include pulmonary histoplasmomas (lung nodules), which are granulomas in the peripheral lung fields that become encased in dense fibrous tissue, often with concentric layers of calcification. These may enlarge over several years and cause symptoms of a mass lesion[170] or manifest as an isolated pulmonary mass. Endobronchial lesions may result in stricture, obstruction, or hemoptysis and mimic bronchogenic neoplasms.[385,389] Unusual histologic features seen in adults may mimic those of lymphomatoid granulomatosis.[310]

Cavitary (also termed *chronic*) pulmonary histoplasmosis rarely has been reported in a child.[37,117] In an analysis of risk factors for cavitary disease in an outbreak estimated to have involved 150,000 persons, only 2 in 170 individuals with cavitary disease were younger than 19 years. Cavitary disease was seen primarily in adults with chronic obstructive pulmonary disease. Symptoms include low-grade fever, productive cough, weakness, weight loss, and fatigue.[173,238] Early pulmonary findings consist of apical interstitial pneumonitis that eventually progresses to fibrosis, cavitation, and gradual spread to uninvolved areas of the lung.[506] If chronic histoplasmosis is untreated, the disease is fatal.[238] Disseminated infection has been reported to develop in approximately 80 percent of patients with this disorder.[146,391]

Primary Cutaneous Histoplasmosis

Numerous reports[335,468] describe immunocompetent patients who present with mucosal,[155,387,415] corneal,[451] or cutaneous ulcerated lesions that show characteristic pathologic changes and morphologic and cultural documentation of *H. capsulatum* and resolve without treatment. These lesions have been considered to be primary, localized infections.[449] Aside from several cases that reasonably may be attributed to documented instances of direct inoculation,[252,415] many of these reports fail to provide sufficient evidence[6,136] to exclude low-grade, chronic dissemination with histoplasmosis.[506] Comprehensive clinical and laboratory evaluations as well as long-term follow-up[90,534] are needed to confidently attribute mucocutaneous lesions to localized infections with *H. capsulatum.*

Progressive Disseminated Histoplasmosis

Progressive disseminated histoplasmosis (PDH) occurs most frequently in immunodeficient patients and patients at the extremes of age.[169,506,513] The clinical entity is defined as an illness that is accompanied by active replication of *H. capsulatum* in multiple organ systems. Symptoms are prolonged and usually last longer than 3 weeks. Laboratory evidence of dissemination may include anemia, thrombocytopenia, and/or leukopenia; persistent antigenuria or antigenemia or both; demonstration of granulomas in extrapulmonary tissue; histopathologic demonstration of compatible yeast; or growth of the fungus in culture.[486] This definition excludes the transient fungal dissemination that uniformly occurs in early primary infection and is aborted by the host's acquired cellular immune response. It does encompass, however,

the rare instance in which intense exposure to a large fungal inoculum results in severe primary infection that overwhelms the host's ability to mount an effective cellular immune response, allowing the usually self-limited primary dissemination to progress.

Distinct clinical presentations of PDH in adults permit subclassification into acute, subacute, and chronic forms. In contrast, PDH in children occurs almost exclusively as an acute, progressive, life-threatening infection.[224] Most of these infections develop in immunocompetent infants younger than 1 year or in children with acquired or primary cellular immunodeficiency. Rarely, PDH occurs in an immunocompetent child, usually in association with exposure to a large fungal inoculum.[95] Transplacental infection has been reported to occur in infants of women with PDH complicating HIV infection.[515]

PDH may result from exogenous exposure of a susceptible or immune host or from reactivation of endogenous quiescent foci of infection. Precise differentiation of these mechanisms of pathogenesis is complicated by the risk for reexposure in endemic areas and the relative unavailability of a method that easily distinguishes strain differences in isolates. Although reactivation of infection may occur in an immunosuppressed host,[218,457,466] epidemiologic data in immunosuppressed individuals who reside in areas highly endemic for histoplasmosis favor exogenous exposure as the most common mechanism. Supporting evidence consists of observations showing that rates of PDH in immunocompromised patients increase only during periods in which infection rates increase in the general population and do not increase in interepidemic periods.[355,399,402,463] Using the results of histoplasmin skin testing obtained at the time of diagnosis of malignancy in a large cohort of children, Hughes[211] found that skin test reactivity was absent in all children in whom PDH subsequently developed and that in none of those known to be skin test positive at the time of diagnosis of neoplastic diseases did PDH develop later.

Progressive Disseminated Histoplasmosis of Infancy

PDH of infancy usually affects children younger than 1 year and has been reported to occur in a 6-week-old infant.[263,333] Rare instances of transplacental[515] infection have been reported. It usually is a subacute illness in which symptoms often are reported to have been present for 1 to 12 weeks before the patient undergoes an initial evaluation; as the disease progresses, patients eventually become profoundly ill and usually die unless treated. Early symptoms include variable fever, failure to thrive,[428] and hepatosplenomegaly in almost all instances. Pallor, cough, tachypnea, oropharyngeal ulcerations, lymphadenopathy, gastrointestinal bleeding, or hemorrhagic skin lesions may develop. Abnormalities that are seen frequently in laboratory studies, and inexorably worsen, include anemia, thrombocytopenia, leukopenia,[169,263,372] disseminated intravascular coagulopathy, and marked depression of immunoregulatory cells[79,333]; these abnormalities reflect the overwhelming fungal parasitization of the reticuloendothelial system and often mimic the presenting signs of a lymphoreticular malignancy.[2] The chest radiograph may show signs of focal pneumonitis, mediastinal adenopathy, or miliary disease, but more than 50 percent of chest radiographs are normal at the time the diagnosis is made. Anatomic sites commonly affected are the spleen, liver, bone marrow, lymph nodes, gastrointestinal tract, and adrenal glands.[68,178,267] Abnormalities in the cerebrospinal fluid (CSF) were found in 62 percent of a series of infections in Costa Rican infants.[333]

PDH of infancy was uniformly fatal before effective antifungal agents became available[263]; survival rates are now excellent. In a series of Costa Rican children that included some infants with malnutrition, 90 percent of patients treated with amphotericin B survived; of the four who died, two had received amphotericin B for either 33 or 35 days and thereafter were treated with orally administered ketoconazole. Both families declined further treatment and were eventually lost to follow-up*; each family returned, however, within 5 weeks of their children's discharge, and massive gastrointestinal hemorrhage and recurrent dissemination were seen in both patients. The other two children were gravely ill and died after having received only either two or three doses. In my experience, survival has been 100 percent in an Indiana series of PDH of infancy.

Progressive Disseminated Histoplasmosis in Immunocompromised Hosts

Immunocompromised individuals, including those in whom either a preexisting medical condition or therapy[279] has depressed cellular immunity, are at risk for progressive dissemination if they acquire histoplasmosis.[211] Common predisposing conditions include AIDS,[71] primary immunodeficiency disorders,[207] those receiving immunosuppressive therapy for reticuloendothelial malignancies,[211] organ transplantation,[176,297] rheumatologic disorders,[187] and chronic renal failure.[216] Severe PDH infections have been recognized in patients treated with TNF-α antagonists for inflammatory disorders.[524] This effect seems to be associated most closely with the use of infliximab,[120,132,259,269] a chimeric mouse monoclonal IgG1 antibody directed against soluble and cellular TNF-α that blocks it from binding with its endogenous cell surface TNF-α receptor.[101,148]

In children who are receiving chemotherapy for malignancies, disseminated histoplasmosis can occur during either remission or relapse.[2,211] The most common initial symptom is persistent fever, usually without localizing symptoms and unassociated with toxicity. As the illness evolves, fever persists and liver and spleen enlargement may occur. Laboratory abnormalities include progressively worsening anemia, leukopenia, and thrombocytopenia; disseminated intravascular coagulopathy may ensue. The chest radiograph may be normal.[211] *Histoplasma* antibody assays usually are negative, and the diagnosis can be confirmed most promptly and reliably by using the *Histoplasma* antigen assay of urine or serum.

Another common symptom complex consists of respiratory complaints and tachypnea. In these instances,

*C. Odio, 2007, personal communication.

persistent fever is followed in several days by dyspnea. Chest radiographs, although occasionally normal at the onset of symptoms, show diffuse interstitial infiltrates that progressively worsen.[2] Hypoxemia usually accompanies the symptoms and is progressive. This clinical complex is not specific for histoplasmosis, however, and may be indistinguishable from those caused by *Pneumocystis jiroveci*, cytomegalovirus, various viral respiratory pathogens, other opportunistic fungi, and bacterial septicemia.

The diagnosis of histoplasmosis may often be established promptly and noninvasively with the urine antigen assay. If this assay is negative, histologic examination and culture of a lung biopsy are the most sensitive and specific diagnostic methods and often provide diagnostic information about other potential causes. Examination of bronchoalveolar lavage (BAL) fluid[188] for *Histoplasma* antigen is sensitive and specific in adults but has not been studied adequately in children.

A subacute form of PDH is seen primarily in adults,[506] although in one report of 19 cases it was found in seven infants and one child.[169] The principal clinical features that distinguish the subacute from the acute form of PDH are a history of more prolonged symptoms at initial evaluation, a higher frequency of focal lesions, less pronounced fever, and fewer hematologic abnormalities in the subacute illness. Early complaints are nonspecific and may be present for 1 to 6 months; malaise and weight loss occur frequently. Hepatosplenomegaly is seen almost uniformly, and intestinal ulceration,[232] sometimes with perforation, occurs commonly.

Gastrointestinal histoplasmosis displays protean manifestations, including perforation,[227] that may occur in association with mediastinal histoplasmosis[228] or in the setting of PDH.[227,505] An autopsy study[182] of 93 adults with AIDS in an endemic region identified gastrointestinal histoplasmosis in 12 percent of cases. The terminal ileum often is involved, and findings may mimic those of Crohn disease.[67,430] Colonic lesions may result in bleeding or obstruction[202,410] and may mimic neoplasms.[260] Isolated colonic lesions without evidence of dissemination are rare.[217] Oropharyngeal ulcerations often occur and are large and deep and can mimic neoplasms.[22,136,169] Seventy-five percent of patients have adrenal involvement, which sometimes is unilateral[437]; adrenal insufficiency occurs less frequently but is reported in 15 to 50 percent of adults.[169,174,256,375,424] CNS infections are seen occasionally and may manifest as chronic meningitis, focal mass lesions, or focal areas of cerebritis. Meningitis has been reported to occur in 62 percent of infants with disseminated histoplasmosis. Endovascular infections occur and may affect normal or native valves. The aortic or mitral valves or prosthetic valves most commonly are affected.* Valvular disease generally is typical of fungal endocarditis, with large vegetations and a high frequency of embolic phenomena.[99]

Numerous isolated lesions[40,93,291,451,523] have been described; some occur in the setting of PDH, and others are found to be focal manifestations of infection.[228,385] Vaginal and penile ulcerations, soft tissue nodules, recurrent panniculitis, tenosynovitis, carpal tunnel syndrome, osteomyelitis and arthritis, enteropathies, immune hemolytic anemia, and epididymitis all have occurred.* Although the pace of subacute PDH is slower than that of acute PDH, it is nonetheless fatal in 2 to 24 months if untreated.[169]

Chronic disseminated histoplasmosis is seen almost exclusively in adults, usually in association with cavitary pulmonary lesions.[169] Oropharyngeal ulcers are accompanied by chronic, mild, intermittent constitutional symptoms. A chronic relapsing disseminated form of the disease has been described in two younger patients, 9 and 20 years old, with chronic mucocutaneous candidiasis[140,307,351] and in a child with IFN-γ receptor-1 deficiency.[540]

Progressive Disseminated Histoplasmosis in Human Immunodeficiency Virus–Infected Patients

Histoplasmosis is an AIDS-defining opportunistic infection and commonly occurs in HIV-infected patients residing in endemic areas. Prior to the development of effective antiretroviral therapy, disseminated infection developed in more than 90 percent of HIV-infected adults who acquired histoplasmosis.[501] In 1988, less than 0.5 percent of adult patients with AIDS had disseminated disease.[172] In endemic areas, it has been reported in approximately 5 percent of patients,[192,292,301] and in 21 to 53 percent of patients during epidemic periods.[43,478,501,512]

In a multivariate analysis of risk factors for the development of histoplasmosis in HIV-infected adults residing in endemic areas, receipt of antiretroviral therapy and triazole drugs was associated independently with decreased risk[193,302]; one study found the risk to be increased with positive baseline serology, $CD4^+$ cell counts less than 150/μL, and exposure to chicken coops.[301] Risk factors for death in two large cohorts of adults also have been determined.[91,99,494] Mortality rates were greater in HIV-infected individuals with PDH treated with antifungal therapy compared with HIV-negative patients with PDH; in HIV-positive patients receiving highly active antiretroviral (HAART) therapy in association with antifungal therapy, clinical outcomes were similar to those of patients with PDH unassociated with HIV infection.[453] Comparable studies have not been done in children. In Arkansas, a highly endemic area, histoplasmosis was the AIDS-defining illness in 8 percent of 40 children who acquired HIV in the perinatal period.[406] Histoplasmosis occasionally is seen in nonendemic regions, perhaps because of reactivation of quiescent foci of infection.[21,63,138,397,398]

In HIV-infected adults with disseminated histoplasmosis, early symptoms often are nonspecific; prolonged unexplained fever and weight loss are seen almost uniformly, and respiratory complaints occur in approximately half of patients.[186,224,398,501] Features are not distinctive, and in areas in which *Penicillium marneffei* also is endemic, clinical, laboratory, and radiographic findings often overlap.[261,308] Gastrointestinal symptoms[228]

*References 7, 40, 74, 133, 156, 196.

*References 226, 240, 245, 341, 366, 388, 415, 433, 476.

including perforation and those caused by partial obstruction[410] are reported commonly and usually are nonspecific; abdominal pain, weight loss, and diarrhea occur in 50 to 70 percent of patients.[28,191,194,254,434] Multiple intestinal pathogens may be present along with *H. capsulatum*.[361] Enlargement of the liver and spleen occurs in approximately 25 percent of patients. Ten percent of patients are initially gravely ill with signs of a septic shock–like syndrome.[501] Mucocutaneous lesions[22,339] occur in approximately 10 percent of adult patients and include nonspecific maculopapular rash, papules, nodules, pustules, ulcerative lesions, acneiform lesions, mucosal ulcers, and vegetative plaques.[145,189] Lesions may mimic those of secondary syphilis[347]; histopathologic examination of skin biopsy specimens often is diagnostic. The frequency of skin lesions in a cohort of Brazilian adult patients with disseminated infection was 66 percent, a difference attributed to geographic strain differences.[234] Histologic examination of the digestive tract in an autopsy study in this population identified histoplasmosis in 11.8 percent.[182] An adult series found that patients with AIDS complicated by disseminated histoplasmosis had a substantially higher mortality rate (32% vs. 14%) than those with other opportunistic infections.[94]

Isolated meningoencephalitis in an immunocompetent child is rarely seen.[452] CNS involvement, including meningitis, encephalitis, and focal brain lesions, occurs in approximately 18 percent of patients with PDH complicating HIV infection.* Symptoms include headache, encephalopathy, or complaints arising from focal neurologic abnormalities.[493] Published reports of histoplasmosis complicating HIV infection in children are few; in four HIV-infected children in Indiana, fever was present in all and cutaneous lesions were absent; hepatosplenomegaly was found in one child, and an abdominal mass caused by an infected abdominal lymph node was seen in one child. In adults, initial chest radiographs are normal in approximately 40 percent, show diffuse interstitial or reticulonodular infiltrates in approximately 50 percent, and show localized lesions in approximately 5 percent. Diffuse abnormalities may appear during treatment of individuals whose chest radiographs initially were normal.[398]

With the widespread use of HAART for treating advanced HIV infections, an immune reconstitution inflammatory syndrome has been described.[1,92,316,413] The immunopathogenesis is presumed to result from interaction between HAART-induced improvement of host immune function and residual microbial antigens.[274,384] *H. capsulatum* is among other granuloma-inducing pathogens reported to induce immune reconstitution inflammatory syndrome.[1,48,346,413]

Central Nervous System Infection

CNS manifestations occur in 5 to 10 percent of adults with PDH,[393,493,509] but they also may occur as chronic meningitis without other signs of apparent dissemination.† Clinical manifestations are varied and include chronic meningitis and arachnoiditis, hydrocephalus, focal parenchymal lesions, cranial nerve neuropathy, vasculitis, stroke, and/or diffuse encephalitis. Isolated meningitis in immunocompetent adults has been associated with presenting signs that include headache, signs of meningeal irritation, and mental status changes.[401] Meningitis is seen in association with disseminated infections in children, especially if acquired during infancy.[333] Isolated meningitis caused by histoplasmosis is extremely unusual in an immunocompetent child.[452] In adults, acute or chronic meningitis occurs in 60 percent of CNS infections; isolated or multiple focal lesions affecting the brain[30] or spinal cord,[208] stroke syndromes,[82] and encephalitis constitute the balance of manifestations. Symptoms of meningitis often are present within 6 months of diagnosis but have been reported to be present for 7 years.[157] Meningitis has been reported to occur years after apparent total resolution of PDH.[48,451] This may result from failure of antifungal agents to penetrate the CNS compartment sufficiently to eradicate the infection.[30,453,493] Commonly associated symptoms include headache, altered level of consciousness, confusion, and cranial nerve deficits in 28 to 56 percent of cases.[493]

Diagnosis is problematic in patients with histoplasmal meningitis and no associated manifestations of localized or disseminated infection.[393] It is suspected ante mortem in only 40 percent of cases. A case has been reported with the onset of symptoms 4 years before the diagnosis was confirmed.[38] Symptoms and findings often mimic those caused by other granulomatous infections, sarcoidosis,[493] cerebral vasculitis,[431] neoplasms,[223] or conditions leading to hydrocephalus.[375] CSF findings are nonspecific and include mild pleocytosis,[376] elevated protein, and depressed glucose concentration. The diagnosis is confirmed by isolating *H. capsulatum* from CSF, detecting *Histoplasma* antigen or antibody in CSF, or identifying the organism in non-CNS sites. Although the specificities of culture and antigen methodologies are high, sensitivity is variable. CSF antigen sensitivity is 38 percent in non–HIV-infected patients and 67 percent in HIV-infected patients. CSF antibody is present in 80 to 89 percent of cases; cross reactions with *Cryptococcus* occur in 28 percent of cases.[509]

CNS infection in children is unusual and, when seen, usually is reported in association with dissemination[405,411]; in one series,[333] meningitis was found in 62 percent of cases of PDH of infancy. A chronic, progressive infection of the CNS has been reported in a child.[383] Other reports describe isolated meningitis with focal neurologic abnormalities occurring after an acute respiratory illness,[36] cerebellar ataxia that was diagnosed only presumptively as histoplasmosis,[412] and cerebellar and medullary lesions.[471] A child has been described with a symptom complex of cervical lymphadenitis, CSF pleocytosis, arthritis, and interstitial nephritis.[476]

Presumed Ocular Histoplasmosis Syndrome

The entity termed *presumed ocular histoplasmosis syndrome* consists of a triad of findings: (1) discrete atrophic choroidal scars in the macula or midperiphery ("histo spots"), (2) peripapillary atrophy, and (3) choroidal

*References 15, 16, 43, 223, 287, 398, 493.
†References 38, 247, 391, 300, 424, 493, 509.

neovascularization[418] that can lead to loss of central vision.[78] In contrast to the acute endophthalmitis[166] or choroiditis[342] that occurs as a manifestation of disseminated infection, the abnormalities seen with presumed ocular histoplasmosis syndrome occur in the absence of inflammatory changes in the vitreous or anterior chambers. Smoking, level of educational attainment, and older age have been reported as risk factors for acquisition of presumed ocular histoplasmosis among a cohort of affected adults.[75]

Commonly diagnosed in endemic areas, the cause-and-effect relationship of the findings in presumed ocular histoplasmosis syndrome and histoplasmosis has been based largely on a weak epidemiologic association with histoplasmin skin test reactivity.[46] The clinical syndrome also occurs in individuals residing in nonendemic regions, however.[340,436,474] Little histopathologic evidence supports histoplasmosis as its cause.[244,338,368] A single report detected *H. capsulatum* DNA in cells of an enucleated eye from an affected patient; however, a nonstandardized polymerase chain reaction–based methodology was used (see section on molecular diagnosis). Another isolated report of the ocular syndrome used a nested PCR assay to detect *H. capsulatum* in serum.[201] Presumed ocular histoplasmosis does not seem to occur in children younger than 10 years. In a review of the operative management of the entity were 11 children aged 12 to 18 years and 1 child aged 7 years.[460] A good recovery of vision has been reported to follow surgical removal of the choroidal neovascularization that accompanies this entity.

Illness Caused by Infection with *Histoplasma capsulatum* var. *duboisii*

In patients infected with *H. capsulatum* var. *duboisii*, focal lesions are seen more commonly in bones (usually the femur, ribs, or skull) and skin (cutaneous or subcutaneous).[3] The lungs, gastrointestinal tract, liver, spleen, and lymph nodes rarely are involved. A progressive disseminated form of infection with *H. capsulatum* var. *duboisii* occurs and is associated with pyogranulomatous inflammation involving multiple organs.[84,152,284,517]

RADIOGRAPHIC FINDINGS

The radiographic findings seen most commonly in children with histoplasmosis are not pathognomonic[149,246] and may mimic the findings seen in tuberculosis or other granulomatous processes and, in some instances, neoplastic conditions,[359] especially lymphoma.[149] After small or moderate degrees of fungal exposure, the plain chest radiograph is normal in approximately 75 percent of skin test converters.[168,514] Computed tomography (CT) is more sensitive and likely to reveal parenchymal infiltrates that are not visualized in plain radiographs. The most common pulmonary parenchymal changes are "soft" single or multiple, poorly defined areas of airspace consolidation[184] often found in the basilar portions of the lungs (Fig. 203-2). CT may also reveal a "reversed halo" sign.[290] Findings either may fully resolve or consolidate into granulomas that persist, with or without calcification, in residents of, or travelers to, endemic areas.[336]

The appearance of enlarged hilar/mediastinal nodes, either in association with pulmonary infiltrates or as isolated findings,[440] also is a common radiographic finding of acute pulmonary histoplasmosis. Isolated hilar or mediastinal adenopathy occurs in 20 percent of cases, 80 percent of which are asymptomatic.[88] With CT, low signal intensity within nodes sometimes is present; however, frank suppuration is unusual. Infected nodes may enlarge and compress or obstruct adjacent structures. Nodes usually have reached their maximal size at the time of diagnosis and become smaller or return to normal in several months; calcification may, but does not consistently, occur. In infants and young children, clusters of small infiltrates occasionally coalesce into a larger bronchopneumonic lesion.[168] Although small pleural effusions are present in 10 percent of adults with acute histoplasmosis,[510] they occur infrequently in children.[2,369,459] Isolated calcifications may be seen in the spleen or liver months to years after infection. These calcifications result from the self-limited fungal dissemination that occurs during primary infection and often are appreciated as incidental findings in individuals who have lived in or visited endemic regions.

Three distinct chest radiographic patterns have been described in individuals who have had intense exposure to the fungus.[168] Individuals from nonendemic areas initially may have scattered infiltrates that later evolve into "buckshot" calcifications. The second and most common pattern is the presence of smaller, nodular lesions (Fig. 203-3). This form is often seen in individuals from endemic and nonendemic areas. Finally, a diffuse miliary or interstitial pattern (Fig. 203-4) may occur, often in a patient with protective immunity. In PDH, the chest radiograph in adults may show abnormalities in only 25 to 50 percent of patients.[87] Diffuse abnormalities commonly appear during treatment of individuals for whom chest radiographs initially were normal.[398] Diffuse interstitial or reticulonodular infiltrates are present in approximately 50 percent, and localized lesions are present in the remainder. In immunocompromised children, diffuse interstitial infiltrates are the most common radiographic findings; they worsen rapidly and in concert with progressive hypoxemia, especially in patients with HIV infection or those receiving immunosuppressive therapy.[87] The presence of interstitial infiltrates at admission has been reported in 60 percent of children with PDH of infancy[333] in a Costa Rican series, but in my experience chest radiographs were normal in a series of Indiana patients. Abdominal ultrasound evaluation or CT, or both, may show evidence of adrenal enlargement in chronic disseminated disease in adults.[29,521]

Fibrosing mediastinitis caused by histoplasmosis is seen radiographically as pronounced thickening of the mediastinum that often compresses or obstructs the superior vena cava, major bronchi, esophagus, and/or other critical structures. It can be found in a localized pattern that frequently contains calcification. It must be differentiated from idiopathic fibrosis or fibrosis not induced by infection, which may cause similar symptoms.[414] CT and magnetic resonance imaging help differentiate active

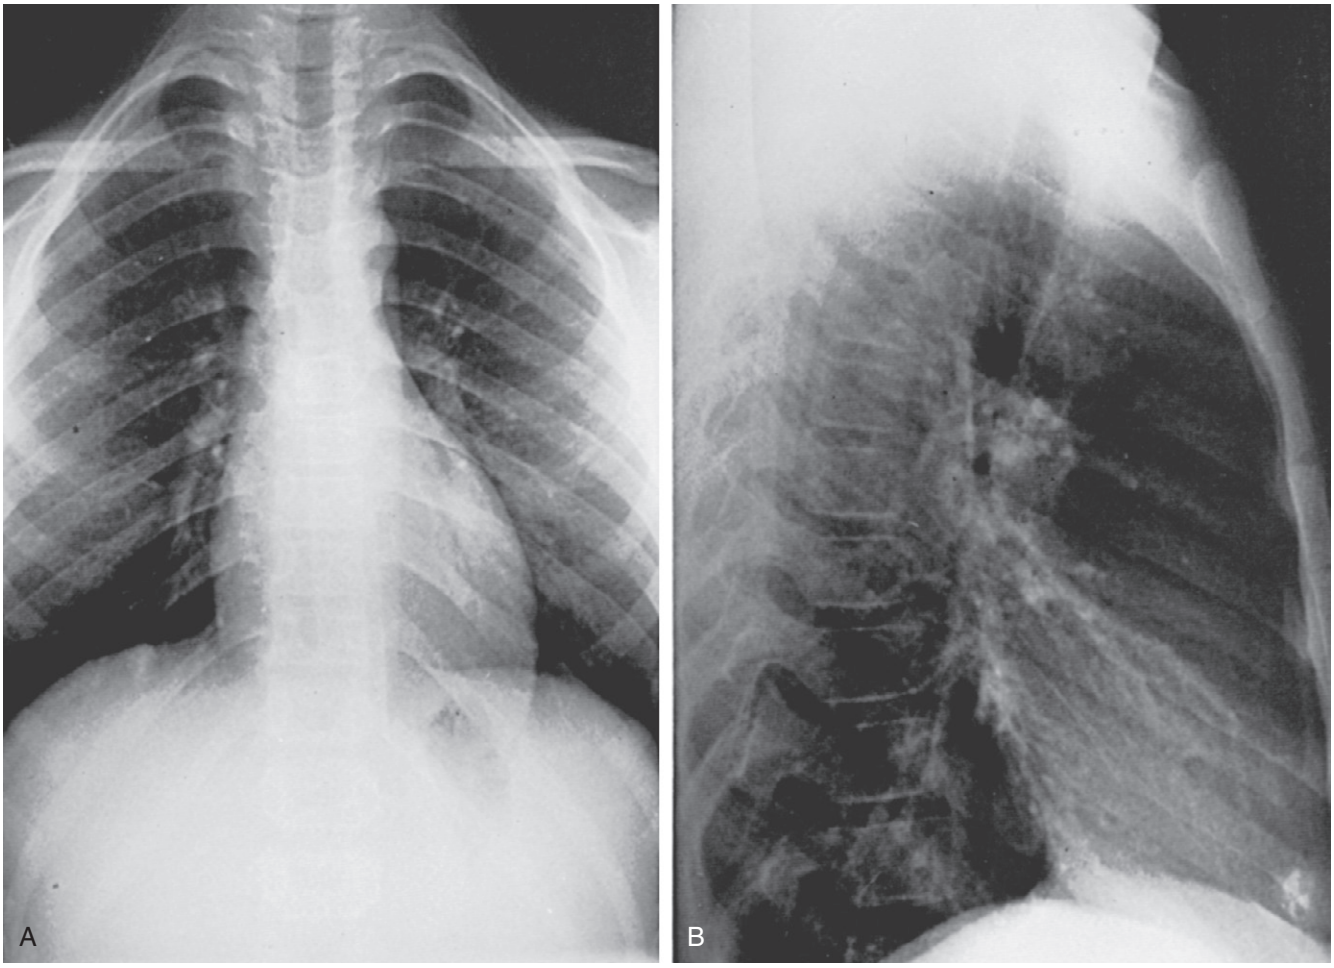

FIGURE 203-2 ■ Chest radiographs of an asymptomatic boy show a calcification in the right lower lobe overlying the diaphragm between ribs 10 and 11 in the posteroanterior view **(A)** and overlying the apex of the heart in the lateral view **(B)**. Punctate calcifications were found overlying the spleen and right axilla (not shown here).

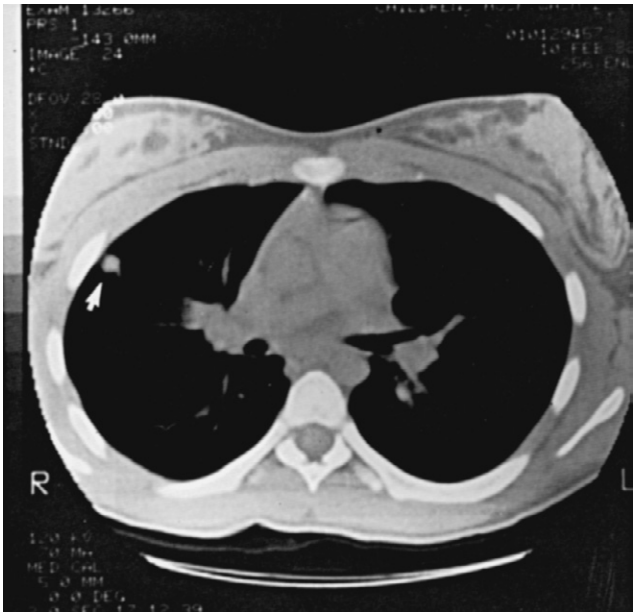

FIGURE 203-3 ■ CT scan of the chest of a teenage girl from Tennessee complaining of right arm pain when swimming. A nodular density is seen in the periphery of the right lung field *(arrow),* and the right hilum is enlarged slightly. Serologic tests and needle biopsy of the lesion were nondiagnostic, but excisional biopsy showed necrotizing granulomas with numerous histoplasmal yeast forms.

FIGURE 203-4 ■ CT scan of the chest of a 16-year-old with a history of recent demolition and renovation in the home. The patient developed fever, cough, and progressive respiratory failure requiring maximal ventilatory support using an oscillator. Note diffuse interstitial infiltrates and a pleural effusion. A urine *Histoplasma* antigen assay was strongly positive.

inflammation from fibrosis and aid in monitoring progression.[386,390] In my experience during a period of 36 years, diffuse mediastinal fibrosis caused by histoplasmosis has been confirmed in only one child in a highly endemic region.

DIAGNOSIS

Several laboratory tests play key roles in establishing the diagnosis of histoplasmosis. Although each has value, their optimal use necessitates an understanding of their differing sensitivities and specificities in various clinical settings.[490] General guidelines for their interpretation are provided in Table 203-2.

Organisms Shown on Histology

In clinical and epidemiologic settings compatible with histoplasmosis, observation of 2- to 4-μm typical yeast forms[183] in histopathologic specimens demonstrating granulomatous inflammation[310] is strong supportive evidence of histoplasmosis (Fig. 203-5). Rarely, typical yeast may be observed but result from past infection.[490] Care must be taken to differentiate *H. capsulatum* from the intracellular pathogens *Leishmania donovani* and *Toxoplasma gondii*, small variants of *Blastomyces dermatitidis*, endospores and young spherules of *Coccidioides immitis*, *P. marneffei*, and the yeast forms of *Cryptococcus neoformans*. Both Giemsa- and hematoxylin and eosin–stained specimens show intracellular yeasts in sputum, blood smears, bone marrow aspirates, and biopsy specimens. The

Modified from Wheat LJ. Improvements in diagnosis of histoplasmosis. Expert Opin Biol Ther *2006;**6**:1207-21.*

Gomori methenamine silver stain is the most sensitive reagent and has the added advantage that calcification artifacts dissolve during the staining procedure[332]; its disadvantage is that it does not provide adequate cellular detail.

Although observation of typical yeast forms in specimens provides important diagnostic information, it requires either a body fluid with a large fungal load or tissue that must be obtained by biopsy. Test sensitivity (Table 203-3) is better in disseminated forms of histoplasmosis, in which yeasts are readily observed in bone marrow, in affected tissue, and often in blood smears.[223] It is less sensitive in self-limited primary infections,[518] including acute pulmonary infection following heavy exposure, in which cytology and histopathology sensitivities are 25 percent.[490] Histopathologic demonstration of typical yeast forms ranged from 18 to 62 percent in three large Indianapolis outbreaks.[490] The technique usually is unrewarding in patients with calcified and/or fibrotic lesions.[286,292,518]

Culture

Normally, sterile specimens and minced or homogenized tissue can be inoculated onto suitable media, such as brain-heart infusion agar, inhibitory mold agar, Sabouraud glucose (dextrose) agar, and enriched broth such as brain-heart infusion broth. The optimal method for recovery of *H. capsulatum* from blood is the lysis-centrifugation technique,[337] which lyses white blood cells, inhibits complement, and prevents coagulation. After processing is completed, the resulting concentrate is transferred to culture media. Specimens from nonsterile sites should be cultured on media that inhibit bacteria and saprophytic fungi; non–cycloheximide-containing media also should be used to permit the growth of other opportunistic pathogens. Cultures are incubated aerobically at 25°C to 30°C and held for at least 12 weeks before being considered negative. Most isolates grow in 3 to 4 weeks.[209,480] Use of the lysis-centrifugation system for blood culture has shortened the time required for identification of a positive culture from approximately 16 days to 9 days.[42,352] The fungus is recovered in its mycelial form, and confirmation of identification necessitates conversion to the yeast form, being shown to produce the H or M exoantigen or reacting positively with a specific nucleic acid probe.[431] Laboratory-based rapid identification and differentiation of fungal pathogens using polymerase chain reaction methodology have been developed, but they are not yet available in clinical laboratories.[144,367,370]

Recovery of *H. capsulatum* from a clinical specimen obtained from a symptomatic patient with a compatible illness confirms the diagnosis of active histoplasmosis. The only exception is the infrequent event in which an incidental granuloma is found to be culture positive, but active histoplasmosis is not a likely cause of the clinical symptoms. The sensitivity of culture varies in direct proportion to the severity of the infection and the fungal burden (see Table 203-3).[519] In primary acute, self-limited histoplasmosis, 40 percent of patients have positive cultures when obtained from sputum (23%), BAL fluid (39%), lung, and extrapulmonary sites (37%).[490] In contrast, cultures are positive in 75 to 85 percent of adults with PDH. In the latter patients, sites from which *H. capsulatum* commonly is recovered include the lower respiratory tract, blood, bone marrow, CSF, liver, spleen, skin lesions, and synovium of affected joints.[253,333] The highest yield in PDH is from bone marrow, which is positive in 75 percent of instances.[399,488] Urine is positive in 40 to 70 percent, and sputum is positive in 60 percent.[424] In adults with PDH, rates of positive lysis-centrifugation cultures of peripheral blood are 90 to 100 percent in acute dissemination and 50 percent in subacute dissemination; positive cultures are very rarely seen in chronic dissemination.

In forms of pulmonary histoplasmosis other than low-inoculum infection, sputum may be a reliable site for recovery of the organism in culture but not the best choice among diagnostic methods. High-inoculum infection after exposure to heavily contaminated sites usually results in moderate-to-severe infection in which patients seek medical attention within 2 weeks of exposure.[70] In these instances, the fungal burden is high and specimens of respiratory secretions and/or lung tissue may show the organism, allowing the diagnosis to be made promptly; culture also may be positive, but the 2- to 4-week delay in achieving growth renders culture less desirable than other diagnostic methods, especially antigen detection. In adults with chronic cavitary pulmonary infection, sputum culture is positive in 50 to 85 percent of instances.[167,491] The sensitivity of sputum culture may be increased with multiple sampling.

Bronchoscopy with BAL may be helpful in patients with pulmonary disease. In a study of bronchoscopy in 71 adults, BAL was positive in only 4 percent of individuals with a single pulmonary nodule, but it increased to 55 percent in the remainder of the patient group. The highest yield of 88 percent (in 7 of 8 patients) occurred in the presence of infiltrates or cavitary disease.[369] Bronchoscopy did not appear to be helpful in evaluating patients with adenopathy, chronic pleural effusion, or bronchopleural fistulas. In children, culture plus staining of BAL fluid has been rewarding in diagnosing high fungal burden infection in patients with HIV, but it is less sensitive than lung biopsy in other immunocompromised patients, especially those receiving chemotherapy for reticuloendothelial malignancy. In adults with

mediastinal granuloma and fibrosis, cultures were positive in only 3.8 to 10 percent.[113,282]

Cultures usually are negative in rheumatologic manifestations of histoplasmosis, such as arthritis, erythema nodosum, erythema multiforme, and pericarditis. This is presumed to result from the fact that these reactive manifestations usually occur months after low-burden infection in patients whose acquired cellular immune response has controlled fungal replication. Isolated CNS infection is uncommon in children, but meningitis has been reported to occur in 25 of 40 cases of PDH of infancy; yeasts were observed in the CSF, and *H. capsulatum* was recovered in culture from four patients.[333] Recognizing CNS infection in adults is difficult unless concurrent dissemination, which occurs in 20 to 40 percent of cases, is also present.[491,493,509] Invasive procedures sometimes are needed to confirm the diagnosis.[377] In adults, culture has been reported to be positive in 27 to 65 percent of CSF specimens and in 50 percent of cultures obtained from other sites.[491] The number of organisms in CSF is small, so the yield is improved substantially by culturing large volumes (10 to 20 mL in adults) on at least two occasions.[509] In isolated CNS infections, culture is usually unrewarding.

Antibody and Antigen Detection

The serologic methods that are used most commonly for the diagnosis of histoplasmosis are immunodiffusion (ID) and CF. These tests are useful because, despite documentation of skin test reactivity in 50 to 70 percent of young healthy adults residing in an endemic area, seropositivity in this population has been found to be 0.5 percent by ID and 2 percent by CF using the mycelial antigen and 4 percent with the yeast antigen. Therefore, if these test results are elevated, they serve to substantially increase the probability of acute or recent histoplasmosis when performed in a patient with a compatible illness.

Both serologic methods have equal sensitivity (75% to 85%); however, ID is slightly more specific (>95% vs. 85% to 90%).[488,489] In immunocompetent patients, either or both tests are positive in 95 percent of patients with acute primary pulmonary infection. CF titers often become positive 2 to 4 weeks earlier, usually within 4 to 6 weeks after exposure.[488] In patients with CF antibody, 25 percent have a negative ID result; only 1 percent of patients reactive by ID are CF negative.[96] When the ID test is reactive, however, it remains so for a longer period of time. In addition to the 4- to 6-week lag in developing elevated titers, an important limitation of both serologic assays is their reduced sensitivity in immunosuppressed patients. Only 50 percent of immunosuppressed children and adults with disseminated histoplasmosis are seropositive.[96,211] Of immunocompetent infants and young children with severe PDH during infancy and early childhood, 93 percent had elevated antibody titers.[333]

Cross reactivity with other fungal antigens affects CF and ID assays.[480] CF cross reactivity occurs most commonly with *B. dermatitidis* (40%) and *C. immitis* (16%).[480] Cross reactions also occur, albeit rarely, with candidiasis, tuberculosis, aspergillosis, and cryptococcosis.[286,480] Cross reactions with blastomycosis are common in the histoplasmosis CF assay, in which titers of 1:8 to 1:16 frequently are observed; comparison of results of a single serum sample performed in the same assay often reveals CF antibody concentrations to be higher for the homologous infection. In these instances, ID tests sometimes are corroborative because the blastomycosis ID method is more specific and less likely to cross react in histoplasmosis.[273] ID has been noted to show false positivity in 5 percent of other fungal infections, however.[480] Cross reactivity also is seen occasionally in patients with chronic cavitary tuberculosis, although simultaneous infection with tuberculosis and fungal pathogens can occur.[147,480] Variability in the specificity of commercial reagents has been reported to cause false-negative results.[264]

Complement Fixation

CF uses sensitized sheep red blood cells, killed whole *H. capsulatum* yeast cells, and histoplasmin, a soluble mycelium-form filtrate antigen. In a common-source outbreak of acute primary pulmonary histoplasmosis, the titer becomes positive in 6 percent of individuals at 3 weeks, 73 percent at 4 weeks, and 77 percent at 6 weeks.[96,480] With resolution of infection, titers decrease to 1:8 to 1:16 within 4 to 6 months and, in most instances, become undetectable (<1:8) by 9 months. Reported sensitivities for a single titer vary from 70 to 95 percent and depend on the threshold for considering a result positive. Single titers of 1:32 performed by an experienced laboratory are strong supportive evidence of acute or recent infection, especially when the accompanying clinical symptoms are compatible. One report[448] showed that 12 of 28 patients with non-*Histoplasma* febrile pneumonia had false-positive CF titers of 1:32 or greater, so other laboratory and clinical data need to be considered.

The demonstration of a fourfold increase between acute and convalescent sera provides the best serologic evidence of recent infection. The individual yeast (CF-Y) and mycelial (CF-M) phases can be measured. The CF-Y phase is more sensitive than the CF-M phase when performed in recent or active infection. In a series of 11 children with acute pulmonary histoplasmosis, CF-Y was 1:32 or greater in 9 children, but the CF-M titer was 1:32 or greater in only 3 children.[529] In highly endemic areas, background low-titer CF serologic reactions may be present in 5 to 15 percent of adults[318] but they have been reported to occur in 30 percent.[158,168,481]

The serologic response seems to correlate with the severity of disease in immunocompetent individuals with acute infection.[257,506] In an extensive outbreak of histoplasmosis, seropositivity was 90 to 100 percent in severe acute histoplasmosis, 86 percent in moderate histoplasmosis, 75 percent in mild histoplasmosis, and 18 percent in asymptomatic histoplasmosis. Twenty-five percent of patients with acute histoplasmosis have CF titers that could be considered borderline positive, between 1:8 and 1:16.[96] Although they may result from previous infection, these titers should not be disregarded if clinical symptoms are compatible with acute infection. In adults with chronic pulmonary histoplasmosis, the CF titer is greater than 1:32 in almost all patients.[149,237] In children

who present with middle mediastinal masses caused by histoplasmosis, 67 percent have CF titers of 1:32 or greater.[149]

The serologic diagnosis of patients with isolated meningitis caused by *H. capsulatum* often is problematic[509] because no single test exhibits high sensitivity. CF and ID can be positive in CSF, but half of patients with other chronic fungal meningeal infections may show false-positive results.[364,479] CF-M antibody seems to be the most sensitive and specific test for the diagnosis of meningitis caused by histoplasmosis. In one study, no false-positive CSF CF-M titers occurred in patients with cryptococcal meningitis but CF-Y was false positive in 5 of 18 patients.[479] Individuals with fibrosing mediastinitis or mediastinal granuloma generally have negative or very low levels of CF antibody.[506]

Immunodiffusion

The micro-ID method detects precipitins (reported as bands) against the H and M glycoprotein antigens of *H. capsulatum*.[481] The M band is present in 25 percent of infections by the fourth week of infection and in 50 to 86 percent by the sixth week.[35,96,356] It can persist for 18 to 36 months after recovery, but eventually becomes nonreactive. In endemic areas, in which serologic surveys show that 24 percent of healthy adult blood donors have CF-Y titers of 1:8 or 1:16, ID serology is positive in less than 1 percent.[158] Because it is more specific, ID can be of value to confirm the diagnosis of histoplasmosis in patients with *Histoplasma* CF titers in the borderline 1:8 to 1:16 range.[473]

The H band is present infrequently in patients with histoplasmosis; when seen, it is transient, and its presence suggests active infection.[168] In patients with active pulmonary histoplasmosis, one half to three fourths have an M band alone. The H band is present in only 10 to 20 percent of acute infections,[173,481] and only 10 percent of individuals have M and H bands present. The presence of both is highly suggestive of active histoplasmosis. The H band is detected less consistently in children with histoplasmosis.[476] In adults with disseminated disease, both bands are present in 25 percent of individuals. The M band has been detected in 52 percent and 57 percent of patients with chronic pulmonary and disseminated disease.[173] The ID test is not approved for use in CSF specimens and has not been evaluated as a test for the diagnosis of meningitis.[490]

Antigen Detection

The development in 1986[507] and further refinements of the *Histoplasma* antigen assay have filled an important gap in laboratory diagnosis. When performed on serum, urine, or other selected body fluids, antigen detection provides rapid, accurate, noninvasive diagnostic information for the most serious manifestations of disease. It is especially useful for the evaluation of infections in immunocompromised hosts, in whom serologic methods often are negative.[507] Although evaluated almost exclusively in adults, antigen detection occupies the same diagnostic niche for managing infection during infancy and childhood.

Antigen detection is most sensitive in infections accompanied by high fungal burdens.[519] These include progressive disseminated infections in intensely exposed or immunocompromised hosts and primary pulmonary infection, in whom antigen detection reflects the early hematogenous dissemination that occurs before being aborted by an effective cellular immune response. In addition to its usefulness in diagnosis, antigen assay provides a quantitative parameter with which to assess the pace and adequacy of response to therapy and, thereafter, a sensitive monitor that promptly detects relapse in patients who are at high risk for recurrence.[497,500,502,503]

The sensitivity of urine antigen detection (see Table 203-3) in patients with acute primary pulmonary infection is 75 to 81 percent, with the highest rates seen in patients tested within a few weeks of exposure, in those with large inoculum exposure, and in patients with extensive pulmonary involvement.[491,518] Sensitivity is less in subacute pulmonary and chronic cavitary infection in adults. The sensitivity of antigen detection is very high in manifestations of progressive disseminating manifestations of histoplasmosis. In adults with disseminated infections, antigen is detected in 91 to 92 percent of immunosuppressed and nonimmunosuppressed patients and in 95 to 100 percent of patients with AIDS.[491,518] In 22 children with PDH, urinary antigen testing was positive in 100 percent.[141] From 1991 through 2011 at Riley Hospital for Children in Indianapolis, I found that urine antigen testing was positive in all instances of disseminated histoplasmosis.

Measurement of *Histoplasma* antigen utilizes a quantitative, third-generation enzyme-linked immunoassay.[127] Although *Histoplasma* antigen can be detected in serum, the sensitivity is substantially less than that of urine. Of immunosuppressed adults with disseminated histoplasmosis, antigen was detected in 50 percent of serum samples and 92 percent of urine specimens. Similarly, in patients with disseminated histoplasmosis complicating AIDS, antigenuria was seen in 95 percent versus 85 percent in serum.[507,518] Antigen often is found in BAL fluid of patients after high inoculum exposure to histoplasmal spores and in immunocompromised patients with hematogenous dissemination and lung involvement.[501,504] In adults with isolated meningitis, antigen detection in CSF may be the sole basis for confirming the diagnosis.[507-509] The range of antigen positivity in all cases of meningitis is 40 to 66 percent; the highest rates are found in severe infections with heavy fungal burdens, especially infections that occur in immunosuppressed patients.[509] In patients with clinical findings suggestive of meningitis but in whom antigen is not present in CSF; antigen detected in extrameningeal sites sometimes can confirm the diagnosis.

Antigen levels in blood or urine decrease during treatment and should clear completely in infections that are treated adequately.[328] Conversely, the persistence of moderate antigenuria has been associated with a risk for recrudescence. This risk has been shown best, but not exclusively,[199] in patients with AIDS and histoplasmosis,

in whom significant antigenuria often persists after cessation of therapy.[372,485,500,502] Monitoring urine antigen in such patients has shown that increasing concentrations foretell recurrence of active infection.[500] The sensitivity of the antigen assay is high, however, and the pattern of antigen clearance has not been established firmly in other clinical settings. Infants with PDH who have been treated adequately, have had a good clinical response, and in whom urine antigen levels have substantially decreased during therapy often have persistence of low levels of urine antigen after completion of amphotericin B therapy. In these infants, all of whom were immunocompetent, I have not observed a relapse after treatment with a total dose of 30 mg/kg of amphotericin B. Residual excretion of urine antigen after adequate treatment continues to decrease and eventually ceases; monitoring is recommended to confirm resolution of antigenuria.[141,372]

With the introduction in 2006 of a third-generation quantitative *Histoplasma* antigen method,[490] interassay variability was reduced by extrapolating antigen concentrations from a calibration curve that was created using the results of assays of known quantities of antigen. Because this calibration curve is linear at values less than a concentration of 40 ng/mL, measurements in excess of this are reported as greater than 39 ng/mL and changes cannot be determined until they fall below this value. Although the quantitative method has increased precision and eliminates the need to evaluate current specimens in tandem with earlier specimens,[490] as required in earlier enzyme-linked immunoassays, it also has necessitated changes in recommendations for using the antigen assay to monitor the effectiveness of therapy.[500] Antigen concentrations in urine measured with the quantitative assay often exceed the upper end of the calibration curve, especially in disseminated infections. If urine concentration exceeds 39 ng/mL, monitoring is more informative if antigen concentrations of serum are initially followed because concomitant serum concentrations are lower than those of concomitant urine samples and more likely to be within the range in which differences in concentration could be measured accurately. Thereafter, when antigenemia is resolved, urine concentrations can be followed with the quantitative assay. Testing should be performed routinely at 3- to 4-month intervals during treatment, at the end of therapy, if symptoms recur, and periodically for another year to monitor for relapse.

Antigen concentration decreases during effective therapy. If the baseline value is less than 20 ng/mL, antigen concentration should decline by 3 ng/mL or more, during the first month and during subsequent 3-month intervals. If the baseline antigen is greater than 20 ng/mL, the concentration should decrease by at least 15 percent during similar time periods. Failure of the antigen concentration to decline or documentation of progressive increase may indicate treatment failure. Persistent but decreasing concentrations of antigenuria may be present after completion of an appropriate and effective course of antifungal therapy. Patients who have completed appropriate courses of therapy for serious infections and have had resolution of their clinical symptoms yet demonstrated persistent but decreasing concentrations of antigenuria have done well after the completion of the planned course of antifungal therapy.[372]

Cross reactions in the *Histoplasma* antigen assay occur in paracoccidioidomycosis, African histoplasmosis caused by *H. capsulatum* var. *duboisii*, blastomycosis, sporotrichosis,[27] and infections caused by *P. marneffei*.[27] Because these infections have distinguishing epidemiologic and clinical features and because supportive diagnostic tests may aid further in differentiating them from histoplasmosis, such cross reactions usually create little difficulty in interpreting positive test results. Because treatment is similar for these endemic mycoses, appropriate therapy may be given while confirmatory diagnostic data are sought. Specimens of blood, urine, BAL fluid, and CSF yield reliable and reproducible results in the antigen assay. False-positive results may occur with pleural fluid and other high protein–containing body fluids, such as peritoneal, synovial, and pericardial fluids; these fluids and tissue specimens are unsuitable specimens. The *Histoplasma* antigen test is commercially available.

Skin Testing

A skin test for histoplasmosis has been a valuable epidemiologic and investigational tool but provided limited diagnostic usefulness[168] for distinguishing past from active infection; it no longer is commercially available. Skin testing was performed with a standardized histoplasmin antigen prepared from a mycelial-phase culture filtrate. After intradermal administration, an area of induration of 5 mm or larger at 48 hours is considered positive and indicative of cellular immunity to histoplasmal antigen. Skin test reactivity usually develops within 2 to 4 weeks after the onset of infection.[146] In chronic pulmonary disease the skin test is positive in three fourths of patients.[146] Individuals with progressive disseminated disease seldom have positive results; this is thought to result from the depression of cellular immune function that accompanies this disease manifestation. Eighty percent of children who are older than 12 years and reside in endemic areas may be reactive.[506] Cutaneous reactivity may diminish, wax, or wane with reexposure[168,506,538] but often persists indefinitely in most individuals. Serologic boosting resulting from intradermal skin testing also limited its diagnostic usefullness.[203,241] Cross reactions occur in patients with blastomycosis and coccidioidomycosis.[131,130]

Molecular Methods

Epidemiologic studies have used restriction fragment length polymorphisms of DNA. Nucleic acid–based and genome-wide approaches have been used to explore the genetic diversity of the pathogen.[242,312,470] Molecular methods also have been used to examine strains recovered from patients who have failed therapy[484] and to identify relatedness in isolates recovered after organ transplantation.[270]

Sensitive and specific oligonucleotide probes for yeast-like fungi have been developed and hold promise for application to clinical specimens.[273] Molecular methods

that reliably detect *H. capsulatum* in clinical samples have yet to show superiority, however, to standard diagnostic tests.[74] Polymerase chain reaction methodology has been evaluated for identifying *H. capsulatum*[31] in tissue and body fluids, but false-negative results were encountered in a third of specimens.[41] Polymerase chain reaction methodology used with clinical specimens (urine, serum, BAL, CSF) containing urine antigen showed specificities of 80 to 100 percent but sensitivities of only 0 to 22 percent.[492] More recent reports show promise for PCR methodology in laboratory identification of *H. capsulatum* in clinical samples.[31,100,144,416]

TREATMENT

The majority of patients with symptomatic histoplasmosis recover without receiving antifungal therapy.[168] Treatment is required for those with severe symptoms, prolonged illness, congenital or acquired immune dysfunction, or signs and/or symptoms suggestive of progressive dissemination. Evidence-based, consensus practice guidelines for treatment of histoplasmosis have been published[486] and revised in 2007[505] to include recommendations for treatment of children.

No controlled therapeutic trials have been conducted in children. Chronic pulmonary infection and subacute and chronic dissemination syndromes rarely occur in children. Recommendations for treating the clinical manifestations of histoplasmosis seen most frequently in children are summarized in Table 203-4. These recommendations have been derived from anecdotal published reports, clinical experience,[372] and extrapolation from experience in adults. Surgical management of complications of histoplasmosis rarely is indicated.[379,476]

Medical Management for Manifestations Requiring Antifungal Therapy

Because most patients with light or moderate exposure to fungal spores recover without treatment, the first decision is to determine whether to observe the patient carefully or to begin administering an antifungal agent. The criteria that are key to making this decision are clinical assessment of the character, severity, and duration of symptoms and assessment of the adequacy of the patient's cellular immunity. When treatment with antifungal agents has been elected, a regimen is selected that is appropriate for the initial findings.[421] Manifestations of histoplasmosis in children that most often require antifungal treatment are severe or protracted symptoms resulting from acute primary pulmonary

TABLE 203-4 **Summary of Treatment Recommendations for Children with Histoplasmosis**

	Treatment	
Manifestation	SEVERE ILLNESS	MODERATE OR MILD ILLNESS
Acute pulmonary	AmB,* 1-2 wk, then Itr for 12 wk†; use of concomitant corticosteroids is controversial	Symptoms <4 wk, none; persistent symptoms for >4 wk, Itr for 6-12 wk
Disseminated (non-HIV) ± meningitis	AmB,‡ or AmB for 2 wk, then Itr for 6 mo‡	Itr† for 6-8 mo or same as for severe§
Disseminated (with HIV)	AmB,‡‖ or AmB followed by Itr§	Same as for severe; Itr secondary prophylaxis if immune dysfunction persists (see text for criteria)
Meningitis, isolated	AmB‖ for 3 mo, then Itr for 12 mo	Some as for severe because of poor outcome
Fibrosing mediastinitis	Itr for 3 mo¶	Same as for severe
Pericarditis	Pericardial drainage for severe tamponade + NSAID for 2-12 wk**	NSAID for 2-12 wk
Rheumatologic	NSAID for 2-12 wk	Same as for severe
Compression of contiguous structures by mediastinal adenitis/granuloma	Prednisone 2 mg/kg/day, concurrent Itr (see text)	

*Amphotericin B deoxycholate is preferred, 1 mg/kg/day.
†In severe manifestations, itraconazole may be given at 150 percent of the recommended dose in three divided doses for the first 3 days of treatment only. Itraconazole levels are recommended for severe infections, and in patients in whom clinical response is suboptimal. Serum levels of 2 µg/mL are recommended when steady state is reached (approximately 2 weeks). Itraconazole dose is 5 to 10 mg/kg/day divided twice a day.
‡If amphotericin B is used for the entire course of treatment, 30 to 40 mg/kg should be given over 4 to 6 weeks.
§Therapy should continue until *Histoplasma* urine antigen concentrations are stable and <4 ng/mL; prolonged low-level excretions may persist (see text).
‖Liposomal amphotericin B (3 to 5 mg/kg/day) may be superior to amphotericin B deoxycholate in patients with HIV (see text).
¶Probably ineffective if fibrotic; when granulomatous mediastinitis could be present, it may be considered.
***Prompt administration of NSAID may obviate need for drainage in non–life-threatening manifestation of pericarditis.*
AmB, amphotericin B; HIV, human immunodeficiency virus; Itr, itraconazole; NSAID, nonsteroidal anti-inflammatory drug (indomethacin 1 to 3 mg/kg/day).
Modified from Wheat LJ, Freifeld A, Kleiman MB, et al. Practice guidelines for management of patients with histoplasmosis. Clin Infect Dis *2007;**45**:807-25.*

infection, mediastinal adenitis that is causing compression of adjacent structures, disseminated infection of infancy,[141,333,372] and infection in an immunocompromised host.[2,435] Treatment recommendations are summarized in Table 203-4.

The antifungal agents that play primary roles in medical management include amphotericin B deoxycholate,[97] liposomal amphotericin B,[225] amphotericin B lipid complex,[358] and itraconazole.[114,482] Amphotericin B preparations are fungicidal for *H. capsulatum*, whereas itraconazole is fungistatic. Combined use of the two agents does not result in synergy. Based largely on the results of its superiority in animal studies[89] and its faster clearance of fungemia in patients with AIDS,[225] amphotericin B is more effective for severe infection than is itraconazole.[372,482] Amphotericin B is used most commonly as "induction" therapy, especially in severe infections; after substantial clinical improvement has occurred, it is stopped and itraconazole is begun to complete treatment.[372] Monotherapy with itraconazole is effective for treating patients who have mild or only moderately severe symptoms. In addition to regimens that are used to treat acute infections, suppressive (secondary prophylaxis) regimens have been developed for treating patients with AIDS because the rate of relapse is high if antifungal treatment is stopped and if immune function has not been improved by HAART.[501] Primary prophylactic regimens also have been developed for use by patients with AIDS who live in highly endemic areas.[299]

A detailed discussion of the antifungal agents used to treat histoplasmosis is presented in Chapter 251. Amphotericin B deoxycholate usually is well tolerated and effective in children. Lipid formulations, although less nephrotoxic, are substantially more expensive.[446] Liposomal amphotericin B is the best evaluated of the lipid preparations. A comparative trial of amphotericin B deoxycholate and liposomal amphotericin B in adults with disseminated histoplasmosis and AIDS showed faster improvement and lower mortality rates with the liposomal preparation.[225] Liposomal, as well as standard, amphotericin B formulations clear fungemia faster than itraconazole does.[495]

If amphotericin B deoxycholate is used as monotherapy for severe or disseminated infection, a dosage of 1 mg/kg/day administered for 4 to 6 weeks is recommended. Failures of 30 and 35 mg/kg total dose have been reported in PDH of infancy,[333] and because relapse has been observed in immunosuppressed patients,[211] close follow-up with monitoring of urine antigen concentrations is required after completion of antifungal therapy. When amphotericin B is used as induction therapy in severely ill children, it should be continued for 2 to 4 weeks and until substantial improvement in clinical and laboratory findings is achieved. Short courses of therapy for PDH of infancy have been successful.[142,263,275] One report described cure in five infants (only two with microbiologic confirmation and another in which PDH was highly probable) with an initial dose of 0.25 mg/kg, 0.5 mg/kg given on the second day, and 1 mg/kg/day administered for 7 to 11 days thereafter.[142] Insufficient data are available to recommend short courses of amphotericin B for treatment as monotherapy; and because of the availability of itraconazole, such regimens seldom are needed.

Itraconazole generally is well tolerated by children and, in adults, is more effective[166] and less likely to induce resistance than the other azoles.* Although formal trials using itraconazole have not been conducted in children, clinical experience has confirmed its effectiveness as the oral azole of choice. The erratic bioavailability of the capsule form can be improved when it is taken with liquids with low pH and caloric content (concomitant food and a cola drink are recommended).[219] Serum levels should be monitored,[162] particularly if symptoms persist. The liquid solution of itraconazole is better absorbed but may have adverse gastrointestinal effects that affect compliance. The liquid solution is better absorbed when taken on an empty stomach. The 90 percent minimal inhibitory concentration (MIC_{90}) of itraconazole for *H. capsulatum* is less than 0.01 μg/mL; the optimal therapeutic level has not been determined, but serum concentrations greater than 2 μg/mL are effective, readily achieved, and well tolerated.[197] With its long half-life, serum concentrations vary little after steady state is achieved (approximately 2 weeks). When used as monotherapy or as step-down treatment after amphotericin B induction to treat mild to moderately severe infections in adults, a loading dose consisting of 150 percent of the total daily dose is recommended for the initial 3 days of therapy. Itraconazole is quite expensive. As with the other azoles, important drug-drug interactions need to be considered in patients receiving agents known to affect excretion of the azole or whose excretion is affected by the antifungal agent.

Fluconazole was less effective than itraconazole in treating adults with chronic pulmonary histoplasmosis[299] or disseminated histoplasmosis.[484] It also has been associated with relapse in disseminated infection,[485] is less effective than itraconazole for secondary prophylaxis in adults with disseminated infection,[302] and clears fungemia more slowly in adults with disseminated infection than does itraconazole.[497] Fluconazole is recommended for use in patients who either do not tolerate itraconazole or fail to absorb it. When fluconazole is used, careful follow-up with urine antigen monitoring is needed to promptly detect relapse. Because itraconazole does not enter the CSF easily, fluconazole may be considered in patients with CNS infection. The relationship between CSF concentrations and outcome has not been determined, however.[486] Antagonism is a concern when fluconazole is used in conjunction with amphotericin B to treat meningitis.[265] Fluconazole is reliably absorbed and metabolized, and drug monitoring seldom is needed.[485]

Ketoconazole is less well tolerated than either itraconazole or fluconazole.[47,112,199,268,458] It is reasonably effective in adults with chronic pulmonary infection[116,268,419,455] and in patients with disseminated infection, although relapse is common.[373] In histoplasmosis complicating AIDS, the response to ketoconazole was only 9 percent versus 74 to 88 percent with amphotericin B and 85 percent with itraconazole.[318,462,485] Ketoconazole is inexpensive and

*References 135, 151, 198, 318, 360, 425, 465.

may be an alternative consideration for treatment if high cost precludes the use of itraconazole.

Both voriconazole and posaconazole have in vitro activity against *H. capsulatum*. Posaconazole has shown greater activity[89,499] and seems to be more active in experimental models. Resistance that seems to have been induced by fluconazole when used in patients with AIDS also was accompanied by an increase in MIC values to voriconazole,[499] suggesting that resistance may emerge during treatment with voriconazole.[498] A recent review of isolates from 208 cases found no development of drug resistance during a 4-year period.[49] Voriconazole* and posaconazole have been effective in isolated reports describing differing manifestations of infection. These agents and fluconazole remain second-line alternatives to itraconazole.[80,362] If these agents are elected for use, therapeutic drug monitoring is recommended.

Primary Pulmonary Infection

Primary pulmonary histoplasmosis that occurs after exposure to a large inoculum of spores may result in life-threatening illness with high fever, diffuse pulmonary infiltrates, hypoxemia, and adult respiratory distress syndrome.[122,168,169,187,486] Infection of this severity should be treated promptly; induction with amphotericin B is indicated and it is continued until substantial clinical improvement occurs. Only anecdotal evidence indicates that concomitant use of corticosteroids may be beneficial in treating patients with severe inhalation and adult respiratory distress syndrome.[175,236,447,533] After improvement resulting from amphotericin B induction, itraconazole should be started and continued for at least 3 months. In patients who may not appear as ill, but in whom laboratory or clinical evidence is suggestive of progressive primary dissemination, empirical therapy should be initiated.

Patients without respiratory distress but in whom systemic complaints, such as fever, fatigue, and weight loss, persist for 2 to 4 weeks or longer also are candidates for antifungal therapy. In these instances, firm criteria to guide the timing of this decision are not established and treatment must be individualized. Still, as observed when amphotericin B was the only effective treatment, and its toxicity and inconvenience resulted in deferring its use for longer than currently practiced, a significant proportion of these symptoms could be expected to undergo spontaneous resolution. The convenience of oral administration of antifungal agents renders the decision less problematic because these protracted but mild to moderately severe symptoms may be treated with itraconazole. Itraconazole should be used for at least 6 weeks in these instances (see Table 203-4). No clinical studies have been conducted to confirm whether treatment shortens the duration of symptoms or prevents later complications.

Mediastinal Adenitis

One of the most common initial presentations of acute illness is the onset of symptoms caused by the mediastinal adenitis that commonly accompanies pulmonary infection caused by *H. capsulatum*. In this setting, affected nodes enlarge, may coalesce, and often compress or obstruct adjacent structures. Bronchi and the trachea are most often affected; less commonly, the superior vena cava and esophagus are affected. The phrenic or recurrent laryngeal nerves[159] rarely are affected. Symptoms usually associated with compression of an airway are cough, mild tachypnea, early exertion with activity, bronchospasm, and nonpleuritic chest pain. The superior vena cava syndrome may accompany obstruction of the superior vena cava. Fever is an uncommon manifestation, unless secondary bacterial pneumonitis caused by airway obstruction is present. The illness generally is self-limited, but symptoms may persist for several weeks. Although only anecdotal evidence supports the benefit of treatment, itraconazole may be helpful for patients with active inflammation. An elevated erythrocyte sedimentation rate and CF titer could be considered markers compatible with active inflammation. As also shown in a study involving dogs with mediastinal granuloma,[404] adjunctive treatment with corticosteroids sometimes is beneficial[175,447] and, if effective, results in prompt improvement. If a corticosteroidal agent is used, it should be given in association with an effective antifungal agent because of the risk for dissemination resulting from corticosteroid-induced suppression of cellular immunity. Itraconazole should be continued for 6 to 12 weeks. Although fibrosing mediastinitis is a late complication of histoplasmosis, no evidence has shown that focal mediastinal adenitis is its precursor and that antifungal therapy prevents its occurrence.

Mediastinal granuloma describes a group of mostly caseous lymph nodes that coalesce into a single lesion usually located in the paratracheal region (Fig. 203-6). It

FIGURE 203-6 ■ A 16-year-old boy was present when a barn was cleaned using a power blower. One week later he developed a low-grade fever followed by intermittent, nonpleuritic, right parasternal chest pain. CT scan of the chest shows a subcarinal mass with central low signal intensity. There is scattered calcification. Histoplasmosis was confirmed by laboratory studies and was compatible with reexposure to the fungus.

*References 4, 143, 208, 317, 380, 456.

affects adults and is very infrequently seen in children. Lesions often are asymptomatic and discovered as incidental findings in imaging studies. Symptoms usually result from impingement of bronchi, the esophagus, or the vena cava. Spontaneous drainage of caseous material may occur spontaneously and result in fistulous tracts to the esophagus,[429] bronchi, or skin. In this setting, treatment with itraconazole is appropriate, although its efficacy in this setting is unproven. Operative intervention or stenting of the affected portion of the superior vena cava sometimes is indicated in the event that compression of vital structures occurs and fails to respond to antifungal therapy. No evidence indicates that this entity is a precursor to mediastinal fibrosis (see section on surgical treatment). There are rare reports of histoplasmosis presenting as tracheal or endobronchial tumors in children.[385]

Disseminated Infection

Progressive disseminated infections in children occur in several settings, and all such occurrences require treatment with antifungal agents.[263,275] Among immunocompetent children, they occur primarily in infants younger than 1 year of age and, albeit infrequently, at any age after high inoculum exposure.[333] Among immunocompromised children, dissemination is seen most often in patients who are receiving immunosuppressive agents that impair the cellular immune system, in patients with AIDS, and less commonly in patients with primary disorders of cellular or combined immunity.[297,540] Treatment recommendations are summarized in Table 203-4.

Immunocompetent Patients and Immunosuppressed Patients Without Human Immunodeficiency Virus Infection

If not treated with antifungal agents,[169,263,275,498] patients with acute PDH have a mortality rate approaching 100 percent.[115,225,482] Treatment with amphotericin B results in survival of more than 90 percent of infants with PDH.[141,211,263,333] In contrast to adults, in whom monotherapy with itraconazole for patients with nonsevere dissemination has been successful,[114,482] only one report[454] has described the outcome of itraconazole monotherapy in children with disseminated histoplasmosis. Seven children 2 to 14 years old were treated. A 2-year-old died "shortly after" treatment was stopped at 1 month. "Marked improvement" was noted in patients treated for 3 months (four patients) and 6 months (one patient), and complete resolution was reported in one patient after 12 months of therapy. Monotherapy with itraconazole is not recommended for disseminated histoplasmosis.[505] Based largely on its demonstrated effectiveness in clinical trials in adults, however, and its ease of administration and tolerability in children, itraconazole is recommended for step-down therapy after induction and clinical improvement with amphotericin B. Serum levels of itraconazole should be monitored (see discussion on antifungal therapy) along with serum/urine antigen concentrations during therapy and in follow-up to confirm that the fungal burden is decreasing.[372] If amphotericin B is elected as monotherapy, a total dose of 30 to 40 mg/kg over 4 to 6 weeks is recommended.

Disseminated Infection in Patients with Acquired Immunodeficiency Syndrome

The severity of the initial signs of illness heavily influences the outcome and the treatment regimens selected for patients with disseminated histoplasmosis complicating HIV infection (see Table 203-4). Regimens are based on trials conducted in adults. Amphotericin B was effective in 74 to 88 percent of all cases,[478,501] whereas patients treated for infections that were sufficiently severe to require hospitalization had a 50 percent mortality rate.[478] In adult patients with moderate-to-severe disseminated histoplasmosis, liposomal amphotericin B provided a survival benefit compared with that of amphotericin B deoxycholate.[225] Adults with only mild or moderate symptoms were treated successfully with itraconazole monotherapy in 85 percent of instances.[482]

Recommendations for children are similar to the recommendations for adults; amphotericin B deoxycholate usually is well tolerated in children and is recommended as monotherapy at a dose of 1 mg/kg/day given for 4 to 6 weeks. Alternatively, it may be used for 2 weeks as induction therapy and, after a satisfactory clinical response, discontinued and followed by itraconazole 5 to 10 mg/kg/day for 12 months. Liposomal amphotericin B, a more costly preparation, may be substituted for the deoxycholate preparation with either regimen in the event of renal complications. Serum, followed by urine, antigen monitoring[328,500] (see discussion of antigen detection) is recommended during therapy and for 1 year after its completion to confirm clearance and, thereafter, to assess for relapse. After the completion of therapy, the significance of low levels of antigenuria in the absence of antigenemia and clinical symptoms is unclear and is not an indication for prolongation of therapy. Prolonged follow-up is recommended in these instances.[372]

Because of a high rate of relapse of histoplasmosis after cessation of antifungal therapy in patients with AIDS complicated by persistently impaired immune function, long-term maintenance therapy (secondary prophylaxis) is recommended.[224,501,511] In adults with mild to moderately severe disseminated infection, amphotericin B (50 mg weekly or biweekly) is effective in 81 to 97 percent of cases,[298,501] and itraconazole is effective in 90 percent.[197,483] Itraconazole is the azole of choice for mildly or moderately ill patients, in whom it may be used as both induction therapy and secondary prophylaxis. Fluconazole is not recommended for secondary prophylaxis (see discussion in the section on medical management) but may be considered if patients received amphotericin B as induction therapy or if itraconazole is poorly tolerated or its cost precludes its use.

A prospective observational study[163] of adults with AIDS and disseminated histoplasmosis found it safe to discontinue secondary prophylaxis after 12 months of primary antifungal therapy and the demonstration of sustained immunologic improvement resulting from HAART therapy. Specific criteria for withholding secondary prophylaxis include negative blood cultures, *Histoplasma* urine antigen concentration of less than

4 ng/mL, and $CD4^+$ T-cell counts greater than 150 cells/μL in patients continuing to receive HAART.[163] Primary prophylaxis with itraconazole is effective for patients with AIDS who live in hyperendemic areas[302] (areas in which the incidence of histoplasmosis is more than 5 cases per 100 patients per year).

Prophylaxis of Immunosuppressed Patients

Clusters of infection occasionally are reported in high-risk populations, sometimes in geographic regions with low background rates.[143] Based on the results of a large clinical trial, however, the need for prophylaxis for patients residing in a hyperendemic area and who are undergoing immunosuppression for management of neoplasms, inflammatory syndromes, or transplantation of allogeneic bone marrow or solid organs[33,417] seems to be low.[463] Included were patients with CF titers to *H. capsulatum* of 1:8 or 1:16, positive M bands by ID, or radiographic evidence suggestive of past infection (calcified splenic or lung nodules). In contrast, patients receiving TNF-α antagonists seem to be at greater risk for developing disseminated histoplasmosis,[420,472,524] perhaps attributable to reactivation of latent infection. Active histoplasmosis during the 2 years preceding the need for immunosuppression may be a basis for consideration of prophylaxis. Although firm evidence is lacking, criteria for such evidence may include chest radiographic findings compatible with histoplasmosis, *Histoplasma* antigenuria, or anti-*Histoplasma* antibody titers of 1:32 or greater. Duration has not been studied, but 12 to 24 weeks has been recommended.[505]

Central Nervous System Infection

With the exception of CNS infections that accompany PDH of infancy, isolated histoplasmosis of the CNS in children[208] rarely is seen.[333,357,452] Adults with CNS infections[30,401] can present with meningitis, focal infection of the brain or spinal cord, thrombotic events caused by focal vasculitis or emboli, or diffuse encephalitis. Active infection in an adult has been reported to be present for 22 years.[157] In children, some infections occur in association with disseminated infection, some as isolated illnesses, and others in the context of relapse involving a sequestered site that is penetrated inadequately by antifungal agents.[509] Mortality is almost certain if meningitis is untreated. Treatment is effective in only 20 to 40 percent of patients with meningitis, and 50 percent of responders experience relapse after cessation of treatment.[247]

Although amphotericin B deoxycholate and liposomal amphotericin B enter the CSF poorly,[123,177,262] liposomal amphotericin B concentrations are higher in brain parenchyma in animal models.[262] Comparative studies of these agents for the treatment of CNS infections caused by *H. capsulatum* have not been performed. In a more recent report,[401] five adults were treated initially with amphotericin B deoxycholate at doses of 40 mg/kg for 8 weeks followed by fluconazole 200 to 400 mg/day for 1 year, resulting in cure of four patients and minor residual sequelae in one. These reports, the ability of liposomal amphotericin B to achieve higher brain tissue levels than occur with amphotericin B deoxycholate, and the superiority of itraconazole over fluconazole in an animal model all contribute to the basis for the recommendation[254] that adults with CNS infections receive liposomal amphotericin B 5 mg/kg/day for 4 to 6 weeks followed by itraconazole for 1 year.

Meningitis was present in 25 of 40 children in a series[333] of PDH. All children received 40 mg/kg of amphotericin B deoxycholate followed by ketoconazole for 3 months. The overall mortality rate in the series was 10 percent; however, two deaths were in children who failed to complete therapy and 2 died within 4 days of presentation, suggesting that this regimen cured meningitis in most cases. In the rare setting in which meningitis is found in a child as an isolated infection, recommendations reasonably might include the use of liposomal amphotericin B (in place of amphotericin B deoxycholate) followed by itraconazole for 12 months.

The role of combination therapy for CNS infection has not been adequately examined in humans. A single case report of histoplasmal meningitis described successful treatment of basilar meningitis caused by histoplasmosis using liposomal amphotericin B and itraconazole.[377] Antagonism has been shown in an animal model[195] that used a regimen of fluconazole and amphotericin B. In another animal model of CNS infection, itraconazole in association with amphotericin B provided no benefit compared with amphotericin B alone.[265]

Despite isolated case reports that have documented success with ketoconazole, itraconazole, fluconazole, the combination of itraconazole and fluconazole, and voriconazole,[456,505] the efficacy of azole monotherapy for the treatment of CNS infections remains inadequately studied. Posaconazole[362,380] has been used successfully as salvage therapy in a patient after therapeutic failure with prior regimens. The evidence is insufficient to recommend azole monotherapy for CNS infection.

Medical Management of Manifestations That Do Not Require Antifungal Therapy

Several common and uncommon manifestations of histoplasmosis do not require antifungal treatment. Apart from mild primary pulmonary infection, one of the most common is pericarditis. Because it rarely is associated with frank fungal infection of the pericardium, it usually resolves spontaneously or with nonsteroidal anti-inflammatory drugs. Indomethacin usually is effective[535] in rapidly reducing inflammation and can reverse signs of impending tamponade. Corticosteroids have been reported to be effective, but, if used, should be accompanied by antifungal therapy. Rheumatologic symptoms of arthritis, with or without erythema multiforme or erythema nodosum, also respond to nonsteroidal anti-inflammatory drugs.[409] Fibrosing mediastinitis is a late complication of histoplasmosis, but it occurs occasionally in children. When granulomatous lesions evolve to become diffusely and densely fibrotic, both antifungal and anti-inflammatory therapies are ineffective. The clinical and laboratory criteria that are used to assess whether active inflammation is present are inexact, however, and

a trial of antifungal therapy often is warranted if clinical features or laboratory evidence of active inflammation, or both, is present. Treatment with antifungal agents almost always is unsuccessful, but improvement has been, albeit rarely, reported.[461] Presumed ocular histoplasmosis is seen almost exclusively in adults and does not improve with antifungal therapy; its management has been reviewed extensively.[78]

Surgical Treatment

Operative intervention rarely is needed to manage patients with histoplasmosis. In a review of 94 patients, 10 to 40 years old, the most common reason for evaluation was obstruction of thoracic structures by mediastinal masses.[153] Seventy-five patients underwent surgery or endoscopy to relieve obstruction of the pulmonary artery, superior vena cava, bronchus, or esophagus. Recurrent pneumonia, tracheoesophageal fistula, hemoptysis, carinal injury, and broncholithiasis were other indications for surgical procedures.[159,153,249,539] Because attempts to excise caseous nodes completely sometimes can damage contiguous structures, the preferable approach is to incise and evacuate debris from such lesions and leave the adherent portion of the capsule intact.[138,153,354,520]

Surgery has little place in the management of fibrosing mediastinitis caused by histoplasmosis. The dense fibrous consolidation of mediastinal structures coupled with the hypervascularity of mediastinal tissues renders the risk for development of hemorrhagic and other life-threatening operative complications high. Excisional biopsy carries a prohibitive risk.[98] Bronchoscopy coupled with coagulation of hyperemic vessels within bronchi in individuals presenting with hemoptysis has been useful.[289] When calcification has occurred in fibrosing mediastinitis, surgical repair is not feasible,[286] and the fibrosis continues after surgery. Some success has been achieved with relief of vascular obstruction by percutaneous placement of intravascular stents,[121,450] but complications occur. I have observed the successful use of an intravascular stent to relieve obstruction in a child with superior vena cava syndrome. Prophylactic excision of enlarged mediastinal nodes has not been shown to prevent fibrosis, and patients with large mediastinal lymph nodes who are otherwise asymptomatic rarely progress to develop mediastinal fibrosis.[506]

PROGNOSIS

Histoplasmosis is either unrecognized or self-limited in the majority of individuals who acquire this most common of the endemic mycoses. Histoplasmosis causes serious illness in infants,[333,371] immunocompromised patients, and older individuals, particularly those with emphysematous pulmonary disease.[45] The cure rate for children who receive therapy for serious acute manifestations is high. Little prospective information is available about the long-term outcome in acute pulmonary histoplasmosis. A study that examined pulmonary function in six children and their parents after intense exposure found restrictive (three patients) and obstructive (two patients) patterns and a reduction in carbon monoxide diffusing capacity in five of six tested. At 2 years, a diffusing capacity abnormality remained in three children and hypoxemia persisted in the most severely affected patient.[250] No data that can help predict the occurrence of long-term complications, such as mediastinal fibrosis, are available. When it does occur, mediastinal fibrosis is progressive and therapeutic options are few.[282] Since, by definition, mediastinal fibrosis impairs the function of both the airways and pulmonary vasculature,[423] its prognosis is influenced heavily by whether it affects one or both lungs.[98] The prognosis is poor in the latter instance.

PREVENTION

Complete prevention of histoplasmosis is currently impossible, but reasonable precautions can substantially decrease the risk to individuals with risk factors that predispose them to serious complications should they acquire the infection. Individuals with impaired cellular immunity who reside in, or plan travel to, endemic regions should be counseled about the potentially serious consequences of infection. This should include education about areas which are endemic for histoplasmosis, sites likely to be heavily contaminated with *H. capsulatum*, and the circumstances, activities, and events that may aerosolize spores and result in inhalation and infection. Primary prophylactic regimens using itraconazole may be considered for HIV-infected patients with exposure to soil mixed with bird or bat droppings (see earlier discussion of epidemiology).[193] If such activities are unavoidable, the use of National Institute for Occupational Safety and Health (NIOSH)–certified high-efficiency mask filtration devices[266] should be encouraged; however, effective devices appropriate for use by young children may be unavailable. Sterilization of sites by formaldehyde spray[266] have been attempted, but the toxicity of this agent renders its use undesirable and, in some settings, ineffective. When potentially contaminated sites, such as old or unused structures in which birds or bats have roosted, are disturbed, aerosols that may contain spores can be substantially reduced by thoroughly dampening the areas with water before they are manipulated.[32] Although educating and counseling high-risk patients affords some protection against acquiring infection from microfoci, some of which can result in intense exposure, this is not helpful in protecting against "sporadic" exposure to contaminated aerosols. For the general population residing in endemic areas, education also is beneficial, particularly for protecting individuals whose occupational and recreational activities may increase their risk for exposure to sites likely to be contaminated with *H. capsulatum*.

Although long an active area of research, vaccines directed against any of the endemic mycoses have not yet been developed. Among the challenges in this effort are both the need to target the general population in an extensive geographic region and to develop a vaccine product that provides lifelong protection, perhaps necessitating repeat immunization.[426] Investigations in animal models[210,330,392] are ongoing in an attempt to identify

vaccine targets[105,111,280,527,532] and to delineate the regulatory elements needed for developing immunity against *H. capsulatum*.[106,400] Investigations in such models have shown that monoclonal antibodies can alter the pathogenesis of histoplasmosis by targeting host costimulatory molecules or fungal cell surface proteins.[331] Another area of inquiry is that of identifying vaccine targets integral to dimorphism, a requisite for the pathogenicity of all the endemic fungi.[319] Additional efforts have explored the feasibility of developing vaccines against invasive fungal pathogens in the setting of severe immunodeficiency, including individuals with $CD4^+$ T-cell deficiency.[532] An animal model has shown that immunization with apoptotic phagocytes that contain heat-killed *H. capsulatum* antigen activated functional $CD8^+$ T cells as well as $CD4^+$ T cells and protected against infection.[210] Biodegradable microspheres that contain leukotriene B4 and cell-free antigens of *H. capsulatum* have been shown to activate murine bone marrow-derived macrophages.[119] A recombinant protein vaccine has been produced from cloned sequences of DNA coding for the cell wall glycoprotein HSP60 and found to be protective in a mouse model against a lethal intravenous inoculum of *H. capsulatum*.[165] This vaccine protected mice in a model of pulmonary infection. Recent experimental data have demonstrated that monoclonal antibodies modify the pathogenesis of histoplasmosis in animal models.[331]

CHAPTER 204

Sporotrichosis

Bernhard L. Wiedermann

Sporotrichosis is an infection caused by the fungus *Sporothrix schenckii* that is manifested most commonly as an ulcerating nodule at a site of local trauma, with spread occurring along regional lymphatic channels. Infection of other tissues or widespread dissemination is rare. It is an uncommon problem in children, but young adults seem to be infected more frequently, presumably owing to more frequent exposure to soil, plants, and decaying vegetable matter that harbor the organism. The disease was described first by a medical student, Schenck, in 1898, and most of what is known about the clinical syndrome has been learned from studies of large outbreaks, particularly one occurring in gold miners near Johannesburg, South Africa, in the early 1940s.[94,108]

ORGANISM

S. schenckii is a dimorphic fungus found principally in decaying vegetable matter or plant debris, although it does not seem to be a plant pathogen. A molecular phylogenetic study of 60 isolates from South America and Europe showed three major clades that tended to group according to geographic origin.[72] The organism grows well on most culture media and is resistant to cycloheximide. Preferred culture media are Sabouraud glucose agar and blood agar, incubated at 25°C to 27°C. Most isolates grow readily from clinical material within 3 to 5 days, although occasional instances of slow growth have been reported, and cultures should be held at least 4 weeks before being considered negative. Incubation on blood agar at higher temperatures (37°C) allows growth of the yeast phase, which is necessary for specific identification of the organism in culture.[87] Another species, *Sporothrix mexicana*, also has caused disease in at least one individual.[25]

EPIDEMIOLOGY

Most cases of sporotrichosis are reported from Central and South America, especially from Mexico and Brazil,
